INTRODUCTION

One-third of the world population is infected with Mycobacterium tuberculosis, but only 5 to 10% of this population has a lifetime risk of developing active tuberculosis, either within 1 or 2 years after infection (primary tuberculosis) or thereafter (postprimary tuberculosis) (Fig. 1). When active tuberculosis develops, disease localization, severity, and outcome are highly variable. Miliary tuberculosis, characterized by the hematogenous dissemination of large numbers of mycobacteria throughout the body, is the most serious disease manifestation. On the other end of the clinical spectrum, tuberculous pleuritis is usually self-limiting. Tuberculosis may develop anywhere in the body, but usually presents as pulmonary infection, ranging from mild infiltration to chronic, cavitary, and severely destructive disease. The different manifestations of infection with M. tuberculosis reflect the balance between the bacillus and host defense mechanisms, in which the quality of host defense determines outcome. In this review, emphasis is placed on the natural, innate host defense mechanisms against M. tuberculosis. However, to enable the reader to place those mechanisms in the context of both innate and acquired defense, a complete picture of M. tuberculosis infection is briefly reviewed first. One should be aware that dissecting innate and acquired host defense mechanisms is an artificial approach. In real life the two components of the host response are complementary and synergistic.

Chronological Events in the Pathogenesis of Tuberculosis

Based on Lurie’s fundamental studies in rabbits (131), four stages of pulmonary tuberculosis have been distinguished (50). The first stage begins with inhalation of tubercle bacilli. Alveolar macrophages ingest the bacilli and often destroy them. At this stage, the destruction of mycobacteria depends on the intrinsic microbicidal capacity of host phagocytes and virulence factors of the ingested mycobacteria. Mycobacteria which escape the initial intracellular destruction will multiply, and this will lead to disruption of the macrophage. When this happens, blood monocytes and other inflammatory cells are attracted to the lung (second stage). These monocytes will differentiate into macrophages which again readily ingest but do not destroy the mycobacteria. In this symbiotic stage, mycobacteria grow log-
FIG. 1. Chronological events after inhalation of *M. tuberculosis*. After inhalation of *M. tuberculosis* (MTB) droplet nuclei, several scenarios may follow. Mycobacteria may be destroyed by alveolar macrophages, in which case no real infection will take place. Alternatively, *M. tuberculosis* may not be immediately killed, and so a primary complex consisting of a small infiltrate and a draining lymph node will develop. Small calcifications may be seen on radiographic examination and the PPD skin test, as a marker of an *M. tuberculosis*-specific T-cell response, becomes positive. Most often, infection is stabilized at this point. In a minority of cases active disease now develops (primary tuberculosis [TB]), either in the lungs or anywhere else after hematogenous dissemination of *M. tuberculosis*. Months or years afterwards, usually under conditions of failing immune surveillance, latent infection may reactivate (postprimary TB).

Protection against Tuberculosis

**Acquired T-cell-mediated immunity.** Elimination of *M. tuberculosis* infection mainly depends on the success of the interaction between infected macrophages and T lymphocytes. Primary as well as acquired immunodeficiencies, especially human immunodeficiency virus infection, have dramatically shown the importance of cellular immunity in tuberculosis. CD4+ T cells exert their protective effect by the production of cytokines, primarily gamma interferon (IFN-γ), after stimulation with mycobacterial antigens. Other T-cell subsets, like CD8+ T cells, are likely to contribute as well, by secreting cytokines and lysing infected cells (79, 214). The T-cell response is mostly antigen specific, and attention has focused on the identification of immunodominant antigens which might be used for the development of effective vaccines (6). The acquired T-cell response develops in the context of the major histocompatibility complex (MHC), and polymorphism of MHC may contribute to differences in disease susceptibility or outcome (27, 82, 178).

Functional diversity of T lymphocytes may also be relevant. In 1986, it was reported that murine helper T (Th) lymphocytes could be divided into two subsets: Th1 clones were characterized by the production of IFN-γ, and Th2 clones were characterized by the production of interleukin 4 (IL-4) (143). Both subsets develop from naive T cells, whose differentiation is influenced by the environment: IL-12, produced by activated macrophages and dendritic cells, is the principal Th1-inducing cytokine, while IL-4 promotes induction of Th2 cells (1). More cytokines and different cellular subsets have been included in this Th1-Th2 concept (144), which is thought to be relevant in many disease entities (129). In mycobacterial infection, Th1-type cytokines seem essential for protective immunity. Indeed, IFN-γ gene knockout (KO) mice are highly susceptible to *M. tuberculosis* (44), and individuals lacking receptors for IFN-γ suffer from recurrent, sometimes lethal mycobacterial infections (70, 98, 151). Th2-type cytokines inhibit the in vitro production of IFN-γ (129, 175), as well as the activation of macrophages (7), and may therefore weaken host defense (56). We and others have shown an increase in Th2-type cytokines in tuberculosis patients (23, 59, 199, 218, 234). However, this is not a consistent finding (14, 91, 123, 126), and the relevance of the Th1-Th2 concept in disease susceptibility or presentation remains uncertain.

**Evidence for innate immunity.** Phagocytic cells play a key role in the initiation and direction of adaptive T-cell immunity by presentation of mycobacterial antigens and expression of costimulatory signals and cytokines. In addition, innate defense mechanisms of phagocytic cells may be important, as highlighted in Lurie’s fundamental studies with resistant and susceptible inbred rabbits (131). Seven days after primary infection through inhalation of tubercle bacilli, the lungs of mycobacterium-susceptible rabbits contained 20- to 30-fold more viable mycobacteria than did the lungs of mycobacterium-resistant rabbits (50). Obviously, this difference during early infection cannot be attributed to T-cell immunity. More recently it was found that acquired T-cell immunity in vaccinated mice...
effectively protects them from disseminated tuberculosis but does not prevent the initial pulmonary infection (43, 155).

In human disease, the same holds true. Acquired T-cell immunity after vaccination with Mycobacterium bovis BCG is more effective against disseminated infection than against pulmonary disease (40). Similarly, naturally acquired T-cell immunity does not prevent exogenous reinfection of the lung (239). Thus, local, T-cell-independent host defense mechanisms clearly are involved in protection against pulmonary infection. More epidemiological data support a role for innate immunity in human tuberculosis. For example, in racially integrated nursing homes, infection, as measured by tuberculin skin test conversion, occurred twice as often in black as in white individuals who were equally exposed to active tuberculosis (211). Apparently, innate host defense mechanisms at this early stage were less efficient in black residents. In accordance with this, macrophages from Afro-Americans demonstrate a relative permissiveness for intracellular growth of virulent mycobacteria (47). Support for the relevance of T-cell-independent, intrinsic bactericidal activity of macrophages is also found in genetic studies which have shown associations between tuberculosis and functional gene polymorphism for various macrophage products (18, 19, 247, 248). There is more evidence, from both clinical and experimental studies, to support the relevance of innate immunity in tuberculosis. In the following paragraphs, the various components and processes that make up the innate host response to M. tuberculosis are discussed in more detail.

PHAGOCYTOSIS OF M. TUBERCULOSIS

Alveolar resident macrophages are the primary cell type involved in the initial uptake of M. tuberculosis. After this first encounter, dendritic cells and monocyte-derived macrophages also take part in the phagocytic process (89, 224). Endocytosis of M. tuberculosis involves different receptors on the phagocytic cell (Fig. 2) which either bind to nonopsonized M. tuberculosis or recognize opsonins on the surface of M. tuberculosis. As an example of the latter mechanism, mycobacteria can invade host macrophages after opsonization with complement factor

FIG. 2. Phagocytosis and immune recognition of M. tuberculosis. Various receptors have been identified for phagocytosis of M. tuberculosis (MTB) by macrophages and dendritic cells: complement receptors are primarily responsible for uptake of opsonized M. tuberculosis; MRs and scavenger receptors for uptake of nonopsonized M. tuberculosis. TLRs play a central role in immune recognition of M. tuberculosis. In the context of CD14, TLR2 binds lipoarabinomannan, a heterodimer of TLR2 and TLR6 binds a 19-kDa M. tuberculosis lipoprotein, TLR4 binds to an undefined heat-labile cell-associated factor, and (possibly) TLR9 binds to M. tuberculosis DNA. After binding to TLRs, common signalling pathways lead to cell activation and cytokine production. TLRs are expressed not only at the cell surface but also in phagosomes; therefore, immune activation may occur with or without phagocytosis. On the other hand, phagocytosis alone probably does not lead to immune activation without the involvement of TLRs.
C3, which is followed by binding and uptake through complement receptor 1 (CR1), CR3, and CR4 (2, 93, 195). The relative importance of the various receptors for complement factor C3 is apparent from experiments in vitro, in which the absence of CR3, phagocytosis of *M. tuberculosis* by human macrophages and monocytes is reduced by approximately 70 to 80% (195, 196). For opsonization with C3, the split product C3b should first be generated by activation of the complement system. *M. tuberculosis* also utilizes part of the classical pathway of complement activation by direct binding to C2a, even in the absence of C4b; in this way the C3b necessary for binding to CR1 is formed (198). This mechanism facilitates mycobacterial uptake in environments low in opsonins, such as the lung. Nevertheless, nonopsonized *M. tuberculosis* can bind directly to CR3 (48) and CR4 (253). However, the best-characterized receptor for non-opsonin-mediated phagocytosis of *M. tuberculosis* is the macrophage mannose receptor (MR), which recognizes terminal mannose residues on mycobacteria (195, 197). When uptake by CRs and MR is blocked, macrophages may also internalize *M. tuberculosis* through the type A scavenger receptor (258). Fcγ receptors, which facilitate phagocytosis of particles coated with antibodies of the immunoglobulin G class, seem to play little role in tuberculosis (9).

Enhanced binding of *M. tuberculosis* to epithelial cells or alveolar macrophages may represent a risk factor for developing clinical tuberculosis. Collectins, a structurally related group of proteins that includes surfactant proteins, mannose-binding lectins (MBLs), and Clq, seem to be important in this respect. Surfactant protein A (Sp-A) facilitates the uptake of *M. tuberculosis* (170), through binding to either the macrophages (78), type II pneumocytes (22, 244), or neutrophils (67). Interestingly, it has been reported that human immunodeficiency virus-infected individuals have increased levels of Sp-A in the lungs, and this results in a threefold-greater attachment of *M. tuberculosis* to alveolar macrophages (62). In contrast, another surfactant protein, Sp-D, has been found to block the uptake of pathogenic strains of *M. tuberculosis* in macrophages (69). It may therefore be hypothesized that the relative concentrations of different surfactant proteins correlate with the risk of infection.

Another member of the collectin family, the plasma factor MBL, may also be involved in the uptake of mycobacteria by phagocytic cells. MBL recognizes carbohydrate configurations on a wide variety of pathogens (150) and induces phagocytosis directly through a yet-undefined receptor or indirectly by activation of the complement system (230). Genetic polymorphisms of the MBL gene account for significant variability of serum MBL concentrations in different populations (127). One study has reported elevated concentrations of MBL in the serum of tuberculosis patients (77), and genetic polymorphisms associated with increased production of MBL have been reported to be a relative disadvantage in mycobacterial infections (200).

Although *M. tuberculosis* has a tropism for phagocytic cells, it may also interact with nonprofessional phagocytic cells, such as alveolar epithelial cells (22). This binding may involve fibronectin, a glycoprotein found in plasma and on the outer surface of many cell types (186). Similar to *Mycobacterium leprae* (32), *M. tuberculosis* may bind to epithelial cells since the bacterium produces and secretes the 30- to 31-kDa antigen 85 complex, a member of the fibronectin-binding protein family (246). In addition, a 28-kDa heparin-binding adhesin, produced by *M. tuberculosis*, will bind to sulfated glycoconjugates on host cells (136).

Thus, there are multiple mechanisms for the uptake of *M. tuberculosis*, involving a number of different host cell receptors. Most of these interactions have been demonstrated in vitro, and their relative importance in vivo remains to be shown. Distinct routes of entry of *M. tuberculosis* may lead to differences in signal transduction, immune activation, and intracellular survival of *M. tuberculosis*. For example, Fcy-receptor-mediated phagocytosis is directly linked to an inflammatory response, and binding to CR is not (2). Survival of *M. tuberculosis* after binding to CR1 is better than that after binding to CR3 or CR4 (51). Also, phagocytosis of Sp-A-opsonized mycobacteria by alveolar macrophages suppresses reactive nitrogen intermediates (170), one of the putative effector mechanisms involved in the killing of mycobacteria (8, 36, 158). Likewise, virulent strains of *M. tuberculosis* are phagocytosed through MR, while attenuated strains are not (195), suggesting that this route of entrance is advantageous to the mycobacterium. Indeed, phagocytosis through MR does not trigger O2•− production (10), and *M. tuberculosis* exerts an anti-inflammatory signal through MR (153). In vivo, the possible role of these events in immune evasion by *M. tuberculosis* remains to be determined. Of interest, strong linkage was found with several markers on chromosome 10p13 (204), where the MR gene is located, in a recent genome-wide scan of 245 families with leprosy in India (64).

**RECOGNITION OF M. TUBERCULOSIS:** ROLE OF TOLL-LIKE RECEPTORS

Besides phagocytosis, recognition of *M. tuberculosis* or mycobacterial products is a crucial step in an effective host response. Immune recognition of the major mycobacterial cell wall component, lipoarabinomannan (LAM), appears to resemble that of gram-negative bacterial lipopolysaccharide (LPS) (257). Several circulating factors and receptors are involved. Plasma LPS-binding protein enhances macrophage responses to LPS and LAM by transferring these microbial products to the cell surface receptor CD14 (68). Similarly, soluble CD14 confers responsiveness to both LAM and LPS in CD14-negative cells (252). Of interest, concentrations of CD14 and LPS-binding protein in serum were elevated in patients with active tuberculosis (109).

Toll-like receptors (TLRs) are phylogenetically conserved mediators of innate immunity which are essential for microbial recognition on macrophages and dendritic cells (20, 135, 240). Members of the TLR family are transmembrane proteins containing repeated leucine-rich motifs in their extracellular domains, similar to other pattern-recognizing proteins of the innate immune system. The cytoplasmic domain of TLR is homologous to the signaling domain of IL-1 receptor (IL-1R) and links to IRAK (IL-1R-associated kinase), a serine kinase that activates transcription factors like NF-κB to signal the production of cytokines (159). To date, at least 10 TLRs have been identified; of those TLR2, TLR4, and TLR9 seem responsible for the cellular responses to peptidoglycan and bac-
terial lipopeptides (251), endotoxin of gram-negative bacteria (196), and bacterial DNA (88), respectively.

TLRs are also involved in cellular recognition of mycobacteria (Fig. 2). Through TLRs, *M. tuberculosis* lystate or soluble mycobacterial cell wall-associated lipoproteins induce production of IL-12, a strong proinflammatory cytokine (29). MyD88 (myeloid differentiation protein 88), a common signaling component that links all TLRs to IRAK (159), was found to be essential for *M. tuberculosis*-induced macrophage activation (232). A mutation of TLR2 specifically inhibited *M. tuberculosis*-induced tumor necrosis factor alpha (TNF-α) production; this inhibition was incomplete, thereby suggesting that besides TLR2, other TLRs may be involved (232). In a transfection model using Chinese hamster ovary (CHO) cells (which are relatively deficient in TLR), expression of TLR2 or TLR4 conferred responsiveness to both virulent and attenuated *M. tuberculosis* (134). TLR2, and not TLR4, was necessary for signaling of the mycobacterial LPS LAM (134, 232) and *M. tuberculosis* conferred responsiveness to both virulent and attenuated *M. tuberculosis*. Expression of TLR2 or TLR4 in CHO cells (49, 181) markedly inhibited CpG dinucleotides in bacterial DNA (87, 88).

From several lines of evidence it has become clear that phagocytosis does not lead to immune activation in the absence of functional TLRs (Fig. 2). Even though TLR2 is recruited to phagosomes during phagocytosis (231), cytokine production was eliminated by the expression of a mutant TLR2, but particle binding and internalization were unaffected. Furthermore, the expression of CD14 and TLRs did not alter uptake of mycobacteria, and this also holds for humans. Interestingly, a recent study showed that TLR2 activation directly led to killing of intracellular *M. tuberculosis* in alveolar macrophages in vitro (222). It may be anticipated that genetic polymorphism, or perhaps mutations, in the relevant TLR or the downstream signaling proteins will affect the performance of the innate host response to mycobacteria.

**CYTOKINE PRODUCTION DRIVEN BY *M. TUBERCULOSIS***

**Proinflammatory Cytokines**

Recognition of *M. tuberculosis* by phagocytic cells leads to cell activation and production of cytokines, which in itself induces further activation and cytokine production in a complex process of regulation and cross-regulation. This cytokine network plays a crucial role in the inflammatory response and the outcome of mycobacterial infections (Fig. 3). Several proinflammatory cytokines are discussed here.

**TNF-α.** Stimulation of monocytes, macrophages (233), and dendritic cells (89) with mycobacteria or mycobacterial products induces the production of TNF-α, a prototype proinflammatory cytokine. TNF-α plays a key role in granuloma formation (117, 201), induces macrophage activation, and has immunoregulatory properties (164, 229). In mice, TNF-α is also important for containment of latent infection in granuloma (139). In tuberculosis patients, TNF-α production is present at the site of disease (14, 33, 124). Systemic spillover of TNF-α may account for unwanted inflammatory effects like fever and wasting. Clinical deterioration early in treatment is associated with a selective increase of TNF-α in plasma (16), and quick recovery is associated with a rapid decrease of TNF-α in plasma (100). To limit the deleterious effects of TNF-α (17, 91), systemic production of TNF-α is downregulated (72, 103, 220), and soluble TNF-α receptors which block TNF-α activity are increased (108). KO mice which are unable to make TNF-α (15, 111, 180) or the TNF-α receptor p55 (71, 201) display an increased susceptibility for mycobacteria. In line with this, the use of potent monoclonal anti-TNF-α antibodies in Crohn's disease and rheumatoid arthritis has been associated with increased reactivation of tuberculosis (including miliary and extrapulmonary disease) (115). In human tuberculosis, no TNF-α gene mutations have been found and no positive association has yet been established between gene polymorphism for TNF-α and disease susceptibility (24, 82).

**IL-1β.** A second proinflammatory cytokine involved in the host response to *M. tuberculosis* is IL-1β. Like TNF-α, IL-1β is mainly produced by monocytes, macrophages, and dendritic cells (49, 181). In tuberculosis patients, IL-1β is expressed in excess (193) and at the site of disease (21, 124). Studies with mice suggest an important role of IL-1β in tuberculosis: IL-1α and -1β double-KO mice (250) and IL-1R type I-deficient mice (which do not respond to IL-1) display an increased mycobacterial outgrowth and also defective granuloma formation after infection with *M. tuberculosis* (106). In addition, among 90 Hindu tuberculosis patients in London, haplotypes for IL-1β and IL-1R antagonist (IL-1Ra) (a naturally occurring antagonist of IL-1) were unevenly distributed: a “proinflammatory haplotype,” reflected in an increased ratio of IL-1β production to IL-1Ra production, was significantly more common in tuberculosis pleurisy than in other types of tuberculosis (248). Because tuberculosis pleurisy is a usually self-resolving type of primary tuberculosis, one may hypothesize that an increased IL-1β/IL-1Ra ratio protects against a more severe presentation of tuberculosis.

**IL-6.** IL-6, which has both pro- and anti-inflammatory properties (237), is produced early during mycobacterial infection and at the site of infection (97, 124, 161). IL-6 may be harmful in mycobacterial infections, as it inhibits the production of TNF-α and IL-1β (194) and promotes in vivo growth of *Mycobacterium avium* (203). Other reports support a protective role for IL-6: IL-6-deficient mice display increased susceptibility to infection with *M. tuberculosis* (121), which seems related to a deficient production of IFN-γ early in the infection, before adaptive T-cell immunity has fully developed (192).

**IL-12.** IL-12 is a key player in host defense against *M. tuberculosis*. IL-12 is produced mainly by phagocytic cells, and phagocytosis of *M. tuberculosis* seems necessary for its production (75, 122). IL-12 has a crucial role in the induction of IFN-γ production (162). In tuberculosis, IL-12 has been detected in lung infiltrates (33, 219), in pleurisy (254), in granulomas (21), and in lymphadenitis (126). The expression of IL-12 receptors
is also increased at the site of disease (255). The protective role of IL-12 can be inferred from the observation that IL-12 KO mice are highly susceptible to mycobacterial infections (45, 241, 242). In humans suffering from recurrent nontuberculous mycobacterial infections, deleterious genetic mutations in the genes encoding IL-12p40 and IL-12R have been identified (3, 5, 53, 73). These patients display a reduced capacity to produce IFN-γ (166). Recently, an IL-12R defect has also been identified in a patient with abdominal tuberculosis (4). Apparently, IL-12 is a regulatory cytokine which connects the innate and adaptive host response to mycobacteria (162, 207, 228) and which exerts its protective effects mainly through the induction of IFN-γ (45).

IL-18 and IL-15. In addition to IL-12, two cytokines are important in the IFN-γ axis. IL-18, a novel proinflammatory cytokine which shares many features with IL-1 (58), was initially discovered as an IFN-γ-inducing factor, synergistic with IL-12 (162). It has since been found that IL-18 also stimulates the production of other proinflammatory cytokines, chemokines, and transcription factors (149, 176). There is evidence for a protective role of IL-18 during mycobacterial infections: IL-18 KO mice are highly susceptible to BCG and M. tuberculosis (216), and in mice infected with M. leprae, resistance is correlated with a higher expression of IL-18 (118). IL-18's major effect in this model seems to be the induction of IFN-γ. Indeed in tuberculosis pleurisy, parallel concentrations of IL-18 and IFN-γ were found (238). Also, M. tuberculosis-mediated production of IL-18 by peripheral blood mononuclear cells is reduced in tuberculosis patients, and this reduction may be responsible for reduced IFN-γ production (238). IL-15 resembles IL-2 in its biologic activities, stimulating T-cell and NK-cell proliferation and activation (60, 116). Unlike IL-2, however, IL-15 is primarily synthesized by monocytes and macrophages. IL-15 mRNA was found to be expressed more strongly in immunologically resistant tuberculoid leprosy than in unresponsive lepromatous leprosy (110). As far as we know, no report has been published yet about IL-15 in tuberculosis.

IFN-γ. The protective role of IFN-γ in tuberculosis is well established (70), primarily in the context of antigen-specific T-cell immunity (6). Mycobacterial antigen-specific IFN-γ production in vitro can be used as a surrogate marker of infection with M. tuberculosis (235). In principal, naive (tuberculin skin test-negative) individuals do not show purified protein derivative (PPD)-stimulated IFN-γ production in vitro (235). However, in both PPD-positive and PPD-negative individuals, M. tuberculosis-infected monocytes stimulate lymphocytes for the in vitro production of IFN-γ (103). We found that PPD (consisting of mycobacterial proteins) selectively induces IFN-γ production in PPD-positive individuals, while M. tuberculosis sonicate, which contains mycobacterial polyglycans and phospholipids, nonselectively induced IFN-γ production in PPD-
positive and PPD-negative individuals alike (R. van Crevel et al., unpublished data). This *M. tuberculosis* sonicate stimulates production of monocyte-derived cytokines like TNF-α and IL-1β (236). These, as well as IL-12 and IL-18, may act as costimuli for antigen-independent IFN-γ production (12, 137, 162).

Which cells are responsible for this nonspecific production of IFN-γ? First, before adaptive T-cell immunity has fully developed, NK cells may be the main producers of IFN-γ, either in response to IL-12 and IL-18 (101) or directly by exposure to mycobacterial oligodeoxynucleotides (76). Second, lung macrophages were found to produce IFN-γ in *M. tuberculosis*-infected mice (242). This remarkable observation needs confirmation. Third, T cells bearing limited T-cell receptor diversity, including T cells expressing γδ T-cell receptors (γδ T cells) and CD1-restricted T cells, may produce IFN-γ during early infection. γδ T cells may directly recognize small mycobacterial proteins (102) and nonprotein ligands (42, 113, 221) in the absence of antigen-presenting molecules. In mice, a single priming with *M. tuberculosis* substantially increases the number of γδ T cells, but not the number of αβ T cells (CD4+ and CD8+ T cells) in draining lymph nodes (102). In mice infected with *M. tuberculosis*, γδ T cells accumulate at the site of disease (85) and seem necessary for early containment of mycobacterial infections (63, 120). Like γδ T cells, CD1-restricted T cells do not react with mycobacterial protein antigens in the context of MHC class I or class II molecules. Instead, these T cells react with mycobacterial lipid and glycolipid antigens bound to CD1 on antigen-presenting cells (141, 142, 174, 205). CD1 molecules have close structural resemblance to MHC class I but are relatively nonpolymorphic. In mycobacterial infections, several different T-cell subsets have been found to interact with CD1, including CD4-CD8- (double-negative) T cells, CD4+ or CD8+ single-positive T cells, and γδ T cells (173, 185, 206). CD1-restricted T cells display cytotoxic activity and are able to produce IFN-γ (213).

**Anti-Inflammatory Cytokines**

The proinflammatory response which is initiated by *M. tuberculosis* is antagonized by anti-inflammatory mechanisms. Soluble cytokine receptors (e.g., soluble TNF-α receptors I and II) prevent binding of cytokines to cellular receptors, thereby blocking further signaling. As already mentioned, IL-1β is counteracted by a specific antagonist, IL-1Ra. In addition, three anti-inflammatory cytokines, IL-4, IL-10, and transforming growth factor beta (TGFβ), may inhibit the production or the effects of proinflammatory cytokines in tuberculosis.

**IL-10.** IL-10 is produced by macrophages after phagocytosis of *M. tuberculosis* (202) and after binding of mycobacterial LAM (49). T lymphocytes, including *M. tuberculosis*-reactive T cells, are also capable of producing IL-10 (13, 28, 81). In patients with tuberculosis, expression of IL-10 mRNA has been demonstrated in circulating mononuclear cells, at the site of disease in pleural fluid, and in alveolar lavage fluid (14, 81). Ex vivo production of IL-10 was shown to be upregulated in tuberculosis by some investigators (95, 227), but this was not found by others (126). IL-10 antagonizes the proinflammatory cytokine response by downregulation of production of IFN-γ, TNF-α, and IL-12 (74, 83, 95). Since the last of these cytokines—as discussed under the previous section heading—are essential for protective immunity in tuberculosis, IL-10 would be expected to interfere with host defense against *M. tuberculosis*. Indeed, IL-10 transgenic mice with mycobacterial infection develop a larger bacterial burden (145). In line with this, IL-10-deficient mice showed a lower bacterial burden early after infection in one report (146), albeit normal resistance in two other reports (66, 154). In human tuberculosis, IL-10 production was higher in anergic patients, both before and after successful treatment, suggesting that *M. tuberculosis*-induced IL-10 production suppresses an effective immune response (28).

**TGFβ.** TGFβ also seems to counteract protective immunity in tuberculosis. Mycobacterial products induce production of TGFβ by monocytes and dendritic cells (226). Interestingly, LAM from virulent mycobacteria selectively induces TGFβ production (49). Like IL-10, TGFβ is produced in excess during tuberculosis and is expressed at the site of disease (41, 226). TGFβ suppresses cell-mediated immunity: in T cells, TGFβ inhibits proliferation and IFN-γ production; in macrophages it antagonizes antigen presentation, proinflammatory cytokine production, and cellular activation (225). In addition, TGFβ may be involved in tissue damage and fibrosis during tuberculosis, as it promotes the production and deposition of macrophage collagenases (225) and collagen matrix (210). Naturally occurring inhibitors of TGFβ eliminate the suppressive effects of TGFβ on mononuclear cells from tuberculosis patients and in macrophages infected with *M. tuberculosis* (92). Within the anti-inflammatory response, TGFβ and IL-10 seem to synergize: TGFβ selectively induces IL-10 production, and both cytokines show synergism in the suppression of IFN-γ production (165). TGFβ may also interact with IL-4. Paradoxically, in the absence of both cytokines, T cells may be directed towards a protective Th1-type profile (65).

**IL-4.** The deleterious effects of IL-4 in intracellular infections (including tuberculosis) have been ascribed to this cytokine’s suppression of IFN-γ production (129, 175) and macrophage activation (7, 56). In mice infected with *M. tuberculosis*, progressive disease (90) and reactivation of latent infection (99) are both associated with increased production of IL-4. Similarly, overexpression of IL-4 intensified tissue damage in experimental infection (130). Conversely, inhibition of IL-4 production did not seem to promote cellular immunity: IL-4−/− mice displayed normal instead of increased susceptibility to mycobacteria in two studies, suggesting that IL-4 may be a consequence rather than the cause of tuberculosis development (66, 154). In contrast, a recent study on IL-4 KO mice showed increased granuloma size and mycobacterial outgrowth after airborne infection (217). Compared with control mice, production of proinflammatory cytokines was increased in these animals and accompanied by excessive tissue damage. We and others have detected increased production of IL-4 in human tuberculosis patients, especially those with cavitary disease (191, 193, 218, 234). However, this is not a consistent finding (14, 91, 123, 126), and it still remains to be determined whether IL-4 causes or merely reflects disease activity in human tuberculosis. Thus, the role of IL-4 in tuberculosis susceptibility is not yet entirely resolved.

Production of soluble cytokine receptors and anti-inflammatory cytokines may help regulate the inflammatory response
during tuberculosis. An unrestrained proinflammatory response may lead to excessive tissue damage (as in IL-4 KO mice), while a predominance of anti-inflammatory effects may favor outgrowth of \textit{M. tuberculosis}. \textit{M. tuberculosis} may evade protective immune mechanisms of the host by selective induction of anti-inflammatory cytokines. In addition, individuals genetically predisposed to higher production of these cytokines may display increased innate susceptibility to \textit{M. tuberculosis}. To date, such genetic predisposition has not yet been reported in humans.

\section*{Chemokines}

Chemotactic cytokines (chemokines) are largely responsible for recruitment of inflammatory cells to the site of infection. About 40 chemokines and 16 chemokine receptors have now been identified (259). A number of chemokines have been investigated in tuberculosis. First, several reports have addressed the role of IL-8, which attracts neutrophils, T lymphocytes, and possibly monocytes. Upon phagocytosis of \textit{M. tuberculosis} (256) or stimulation with LAM, macrophages produce IL-8 (107, 256). This production is substantially blocked by neutralization of TNF-\(\alpha\) and IL-1\(\beta\), indicating that IL-8 production is largely under the control of these cytokines (256). Pulmonary epithelial cells also produce IL-8 in response to \textit{M. tuberculosis} (245). In tuberculosis patients, IL-8 has been found in bronchoalveolar lavage fluid (119, 188), lymph nodes (21), and plasma (72, 107). Patients who died from tuberculosis showed higher concentrations of IL-8 (72). Interestingly, following antituberculous treatment, concentrations of IL-8 remain elevated in alveolar lavage fluid (119) and serum (72) for months. This finding is puzzling, because first of all it is unclear what drives such prolonged production and second IL-8 is a potent neutrophil attractant and a neutrophilic response is not prominent in established tuberculosis.

A second major chemokine is monocyte chemoattractant protein 1 (MCP-1), which is produced by and acts on monocytes and macrophages. \textit{M. tuberculosis} preferentially induces production of MCP-1 by monocytes (112). In murine models, deficiency of MCP-1 inhibited granuloma formation (128). Also, C-C chemokine receptor 2-deficient mice, which fail to respond to MCP-1, display reduced granuloma formation and suppressed Th1-type cytokine production (26) and die early after infection with \textit{M. tuberculosis} (171). In alveolar lavage fluid (119), serum (107), and pleural fluid (138) from tuberculosis patients, concentrations of MCP-1 were found to be elevated. A third chemokine is RANTES, which is produced by a wide variety of cells and which shows promiscuous binding to multiple chemokine receptors. In murine models, expression of RANTES was associated with development of \textit{M. bovis}-induced pulmonary granulomas (37). In human patients, RANTES has been detected in alveolar lavage fluid (119). Apart from IL-8, MCP-1, and RANTES, other chemokines may be involved in cell trafficking in tuberculosis (177). Inhibition of chemokine production may lead to an insufficient local tissue response. However, due to the redundancy of the chemokine system, the contribution of individual chemokines is difficult to evaluate. As far as we are aware, no clear-cut defects of chemokine production have been identified up to now in patients with mycobacterial infectious diseases.

\section*{EFFECTOR MECHANISMS FOR KILLING OF \textit{M. TUBERCULOSIS}}

Macrophages are the main effector cells involved in killing of \textit{M. tuberculosis}. To become active against mycobacteria, macrophages need to be activated. In vitro models of macrophage activation for the killing of \textit{M. tuberculosis} seem rather artificial, and therefore the exact conditions for optimal activation remain unknown. However, it is clear that lymphocyte products, mainly IFN-\(\gamma\), and proinflammatory cytokines like TNF-\(\alpha\) are important. In addition, vitamin D seems involved in macrophage activation.

The active metabolite of vitamin D, 1,25-dihydroxyvitamin D, helps macrophages suppress growth of \textit{M. tuberculosis} (55, 182, 184). Concentrations of vitamin D in serum have been reported to be lower in tuberculosis patients in some populations (52) but not in others (84). A recent study among Gujarati Hindus, a mainly vegetarian immigrant population in London, showed that vitamin D deficiency was a risk factor for tuberculosis (247). When considered in combination with vitamin D deficiency, three polymorphisms of the vitamin D receptor were also associated with disease susceptibility in this population. For another variant of the vitamin D receptor (\(\alpha\) genotype), 6% of tuberculosis patients in The Gambia proved homozygous compared with 12% of control subjects (18), suggesting that this polymorphism protects against active tuberculosis. It should be noted, however, that no functional changes which might affect macrophage activation have yet been described for any of the vitamin D receptor polymorphisms associated with disease.

Putative mechanisms involved in killing of \textit{M. tuberculosis} within the phagolysosomes of activated macrophages include the production of reactive oxygen intermediates (ROI) or reactive nitrogen intermediates (RNI). The study of these mechanisms has been hampered by differences between mice (the most important animal model used for mycobacterial infections) and humans. However, when we restrict ourselves to data derived from human cells or patients, controversy remains. In vitro, mycobacteria seem resistant to killing by ROI such as superoxide and hydrogen peroxide (36). A possible explanation lies in the fact that several mycobacterial products, including sulfatides and LAM, are able to scavenge ROI (35, 148, 168). In vivo, it was found that p47\(^{\text{phox}}^{-/-}\) mice, which lack a functional p47 unit of NADPH-oxidase needed for superoxide production, suffer from increased early outgrowth of mycobacteria in experimental infection (46). Therefore, this supports a role for ROI in the killing of \textit{M. tuberculosis}. On the other hand, patients with chronic granulomatous disease, who have defective production of ROI, do not seem to display increased susceptibility to tuberculosis (249).

The role of RNI in tuberculosis also remains a matter of debate. In vitro, human alveolar macrophages infected with \textit{M. bovis} BCG display increased inducible nitric oxide synthase (iNOS) mRNA (158), and inhibition of iNOS is followed by increased bacterial outgrowth (158). In tuberculosis patients, alveolar macrophages show increased production of iNOS as well (152). However, whether iNOS gene expression leads to in vivo NO production remains uncertain, as in humans post-translational modification of iNOS may be necessary for func-
tional activity (190). Therefore, the exact contribution of RNI in human tuberculosis remains to be elucidated.

Sustained intracellular growth of *M. tuberculosis* may depend on its ability to avoid destruction by lysosomal enzymes, ROI, and RNI. When phagocytosed by macrophages, bacteria typically enter specialized phagosomes that undergo progressive acidification followed by fusion with lysosomes. However, *M. tuberculosis* delays or inhibits fusion of phagosomes and lysosomes (9, 187). In addition, *M. tuberculosis* prevents phagosomal maturation and acidification of phagosomes, thereby blocking the digestive activity of acidic hydrolases (39, 215).

*Nramp1*, which codes for natural-resistance-associated macrophage protein (Nramp), is an interesting gene involved in macrophage activation and mycobacterial killing (25). The protein is an integral membrane protein which belongs to a family of metal ion transporters. These metal ions, particularly Fe²⁺, are involved in macrophage activation and generation of toxic antimicrobial radicals (200). Following phagocytosis, *Nramp1* becomes part of the phagosome. *Nramp1* mutant mice display reduced phagosomal maturation and acidification (86). Surprisingly, mycobacterial outgrowth is unaffected in these animals (156). In humans, functional polymorphism in the promoter region of *Nramp1*, associated with reduced gene expression, was found to be associated with susceptibility to tuberculosis in studies from West Africa (19, 34). Thus, genetic variation in *Nramp1* may affect the outcome of infection with *M. tuberculosis*. However, to prove the significance of this gene in human tuberculosis further epidemiological and mechanistic studies are needed.

Apoptosis may constitute another effector mechanism for the infected host to limit outgrowth of *M. tuberculosis* (114, 172). Apoptosis of phagocytic cells may prevent dissemination of infection. In addition, apoptosis of infected cells reduces viability of intracellular mycobacteria, while necrosis of infected cells does not (140, 160). TNF-α is required for induction of apoptosis in response to infection with *M. tuberculosis* (114). Interestingly, pathogenic *M. tuberculosis* strains induced significantly less host cell apoptosis than related attenuated strains (114). This difference was explained by selective induction and release of neutralizing soluble TNF-α receptors by pathogenic strains (11). Release of TNF-α receptors in turn was regulated by IL-10 production (11). Thus, pathogenic strains of *M. tuberculosis* may selectively induce IL-10, leading to decreased TNF-α activity and reduced apoptosis of infected cells. Independent of cytokine production, LAM may prevent reduced phagosomal maturation and acidification of phagosomes, thereby blocking the digestive activity of acidic hydrolases (39, 215).

Antigen Presentation

Presentation of mycobacterial antigens by macrophages and dendritic cells involves distinctive mechanisms. First, MHC class II molecules present mycobacterial proteins to antigen-specific CD4⁺ T cells. These antigens must be processed in phagolysosomal compartments in professional antigen-presenting cells. Second, MHC class I molecules, expressed on all nucleated cells, are able to present mycobacterial proteins to antigen-specific CD8⁺ T cells. This mechanism allows for the presentation of cytosolic antigens, which may be important as certain mycobacterial antigens may somehow escape the phagosome (132). The importance of MHC class I-mediated antigen presentation has been shown in murine models (208) and tuberculosis patients (38, 79). Third, nonpolymorphic MHC class I molecules such as type I CD1 (α, β, and γ) molecules, which are expressed on macrophages and dendritic cells, are able to present mycobacterial lipidproteins to CD1-restricted T cells. This mechanism allows for nonpolymorphic MHC class Ib molecules (125).

The expression of particular class I and class II MHC alleles in an individual determines the ability of that individual to respond to particular (mycobacterial) antigens and epitopes. Certain allelic human leukocyte antigen (HLA) variants have been associated with tuberculosis (82, 179). HLA polymorphism may explain the vulnerability of certain isolated populations like Amazonian Indians which have only recently been exposed to tuberculosis (209). There is a large body of evidence for similar mechanisms in leprosy. The expression of antigen-presenting molecules is also a dynamic process, which is regulated by cytokines. While proinflammatory cytokines, primarily IFN-γ, stimulate expression of MHC, anti-inflammatory cytokines inhibit its expression. Mycobacteria may modulate the antigen presentation function, but different results have been obtained in vitro with macrophages and dendritic cells. Mycobacteria may downregulate expression of antigen-presenting molecules in macrophages, most likely through the production of anti-inflammatory cytokines (80, 169). On the other hand, MHC expression on dendritic cells is upregulated following *M. tuberculosis* infection (89, 223).
Costimulation

It is well known that antigen presentation only leads to T-cell stimulation in the presence of particular costimulatory signals. The most well-known costimulatory signals for T-cell stimulation are B-7.1 (CD80) and B-7.2 (CD86). These molecules are expressed on macrophages and dendritic cells and bind to CD28 and to CTLA-4 on T cells. Interestingly, in vitro infection of monocytes with *M. tuberculosis* leads to diminished expression of B-7.1 (189). On the other hand, *M. tuberculosis* infection of dendritic cells induces expression of B7.1, CD40, and ICAM-1 (89). In the absence of proper costimulatory signals, antigen presentation may lead to increased apoptosis of T cells (94, 96).

Cytokine Production

Several cytokines produced by activated macrophages and dendritic cells are essential for stimulation of T lymphocytes. Macrophages and dendritic cells produce the type 1 cytokines IL-12, IL-18, and IL-23 (163). In patients with recurrent or fatal nontuberculous mycobacterial infections, functional genetic mutations have been found in the genes encoding IL-12p40 (5, 73), IL-12Rβ1 (53, 166), IFN-γ receptor 1 (98, 105, 151), and IFN-γ receptor 2 (61), all of which are involved in IFN-γ receptor signaling in macrophages and dendritic cells. Clearly the capacity of these cells to produce or react to Th1-type cytokines is necessary for proper T-cell stimulation (Fig. 4). In addition, proinflammatory cytokines like IL-1 (57) and TNF-α (229) have important T-cell stimulatory properties. Reduced production of type 1 or proinflammatory cytokines may delay or decrease T-cell stimulation and the initiation of antigen-specific T-cell immunity. In this respect, the production of anti-inflammatory cytokines may be relevant as well. For instance, in anergic tuberculosis patients it was recently shown that IL-10 production is constitutively present and that T-cell receptor-mediated stimulation results in defective signal transduction (28). TGFβ may have a similar antagonistic role (92, 225).

CONCLUDING REMARKS

The interplay between *M. tuberculosis* and the human host determines the outcome after infection. With respect to the human host, both innate and adaptive defense mechanisms are involved. After uptake of *M. tuberculosis* in alveolar macrophages, several possible scenarios may be envisaged. *M. tuberculosis* may be destroyed immediately, in which case no adaptive T-cell response is developed. When infection is established, however, a focal nonspecific inflammatory response follows. This response is regulated by a network of pro- and anti-inflammatory cytokines and chemokines. Most of the mediators at this point are derived from macrophages or dendritic cells, but IFN-γ has several cellular sources, including NK cells, γδ T cells, and CD1-restricted T cells. This initial response determines the local outgrowth of *M. tuberculosis* (sometimes dissemination) or containment of infection. Phagocytic cells also play a key role in antigen presentation and the initiation of T-cell immunity which follows. At many stages in the host response, *M. tuberculosis* has developed mechanisms to circumvent or antagonize protective immunity.

The interindividual differences in outcome after infection with *M. tuberculosis* may in part be explained by the efficiency of various innate host defense mechanisms. Phagocytosis, immune recognition, cytokine production, and effector mechanisms may all contribute to innate immunity. In this respect, different gene polymorphisms have been found which are associated with increased susceptibility and severity of tuberculosis. Some of these polymorphisms are functional, but for many of these no functional (immunologic) changes have been demonstrated yet, and these associations therefore need further confirmation and investigation.

What remains to be determined is to what extent the encounters between *M. tuberculosis* and the human host can be
modulated. In many settings the most cost-effective way to improve disease outcome is to increase patients’ access to health care facilities and to strengthen the quality of diagnosis and antimycobacterial treatment. However, in many parts of the world the spread of multidrug-resistant tuberculosis seriously threatens the success of antibiotic treatment. Therefore, more-effective vaccines and new therapeutic strategies (like immunotherapy) are desperately needed. It is expected that increased understanding of disease pathogenesis will help the design of such adjunctive treatment, which will undoubtedly benefit the outcome of individual patients and limit the spread of M. tuberculosis around the world.

ACKNOWLEDGMENT

We thank Mihai Netea for fruitful discussions about the subject and review of the manuscript.
