Effectiveness of Preanalytic Practices on Contamination and Diagnostic Accuracy of Urine Cultures: a Laboratory Medicine Best Practices Systematic Review and Meta-analysis

Mark T. LaRocco, Jacob Franek, Elizabeth K. Leibach, Alice S. Weissfeld, Colleen S. Kraft, Robert L. Sautter, Vickie Baselski, Debra Rodahl, Edward J. Peterson, Nancy E. Cornish

BACKGROUND. Urinary tract infection (UTI) in the United States is the most common bacterial infection, and urine cultures often make up the largest portion of workload for a hospital-based microbiology laboratory. Appropriately managing the factors affecting the preanalytic phase of urine culture contributes significantly to the generation of meaningful culture results that ultimately affect patient diagnosis and management. Urine culture contamination can be reduced with proper techniques for urine collection, preservation, storage, and transport, the major factors affecting the preanalytic phase of urine culture.

AUTHOR BIOS
**Objective.** The purposes of this review were to identify and evaluate preanalytic practices associated with urine specimens and to assess their impact on the accuracy of urine culture microbiology. Specific practices included collection methods for men, women, and children; preservation of urine samples in boric acid solutions; and the effect of refrigeration on stored urine. Practice efficacy and effectiveness were measured by two parameters: reduction of urine culture contamination and increased accuracy of patient diagnosis. The CDC Laboratory Medicine Best Practices (LMBP) initiative’s systematic review method for assessment of quality improvement (QI) practices was employed. Results were then translated into evidence-based practice guidelines.

**Search strategy.** A search of three electronic bibliographic databases (PubMed, SCOPUS, and CINAHL), as well as hand searching of bibliographies from relevant information sources, for English-language articles published between 1965 and 2014 was conducted.

**Selection criteria.** The search contained the following medical subject headings and key text words: urinary tract infections, UTI, urine/analysis, urine/microbiology, urinalysis, specimen handling, preservation, biological, preservation, boric acid, boric acid/borate, refrigeration, storage, time factors, transportation, transport time, time delay, time factor, timing, urine specimen collection, catheters, indwelling, urinary reservoirs, continent, urinary catheterization, intermittent urethral catheterization, clean voided, midstream, Foley, suprapubic, bacteriological techniques, and microbiological techniques.

**Main results.** Both boric acid and refrigeration adequately preserved urine specimens prior to their processing for up to 24 h. Urine held at room temperature for more than 4 h showed overgrowth of both clinically significant and contaminating microorganisms. The overall strength of this body of evidence, however, was rated as low. For urine specimens collected from women, there was no difference in rates of contamination for midstream urine specimens collected with or without cleansing. The overall strength of this evidence was rated as high. The levels of diagnostic accuracy of midstream urine collection with or without cleansing were similar, although the overall strength of this evidence was rated as low. For urine specimens collected from men, there was a reduction in contamination in favor of midstream clean-catch over first-void specimen collection. The strength of this evidence was rated as high. Only one study compared midstream collection with cleansing to midstream collection without cleansing. Results showed no difference in contamination between the two methods of collection. However, imprecision was due largely to the small event size. The diagnostic accuracy of midstream urine collection from men compared to straight catheterization or suprapubic aspiration was high. However, the overall strength of this body of evidence was rated as low. For urine specimens collected from children and infants, the evidence comparing contamination rates for midstream urine collection with cleansing, midstream collection without cleansing, sterile urine bag collection, and diaper collection pointed to larger reductions in the odds of contamination in favor of midstream collection with cleansing over the other methods of collection. This body of evidence was rated as high. The accuracy of diagnosis of urinary tract infection from midstream clean-catch urine specimens, sterile urine bag specimens, or diaper specimens compared to straight catheterization or suprapubic aspiration was varied.

**Authors’ conclusions.** No recommendation for or against is made for delayed processing of urine stored at room temperature, refrigerated, or preserved in boric acid. This does not preclude the use of refrigeration or chemical preservatives in clinical practice. It does indicate, however, that more systematic studies evaluating the utility of these measures are needed. If noninvasive collection is being considered for women, midstream collection with cleansing is recommended, but no recommendation for or against is made for midstream collection without cleansing. If noninvasive collection is being considered for men, midstream collection with cleansing is recommended and collection of first-void urine is not recommended. No recommendation for or against is made for collection of midstream urine without cleansing. If noninvasive collection is being considered for children, midstream collection with cleansing is recommended and collection in sterile urine bags, from diapers, or midstream without cleansing is not recommended. Whether midstream collection with cleansing can be routinely used in place of catheterization or suprapubic aspiration is unclear. The data suggest that midstream collection with cleansing is accurate for the diagnosis of urinary tract infections in infants and children and has higher average accuracy than sterile urine bag collection (data for diaper collection were lacking); however, the overall strength of evidence was low, as multivariate modeling could not be performed, and thus no recommendation for or against can be made.

**INTRODUCTION**

The most common infection occurring in the United States is urinary tract infection (UTI), accounting for nearly 7 million office visits, 1 million emergency room visits, and 100,000 hospitalizations per year (1, 2). Significantly more women than men are likely to experience UTIs, with 1 in 3 women having at least 1 episode of UTI necessitating treatment with antibiotics by the age of 24 (3). Nearly half of all women will experience at least one UTI during their lifetime (3–6). An increased risk of UTI occurs in certain population subgroups, including infants (7), pregnant women (8), the elderly (9), patients with spinal cord injuries and/or catheters (10), patients with diabetes (11) or multiple sclerosis (12), and patients with AIDS/human immunodeficiency virus (13, 14). The most common nosocomial infection is catheter-associated UTI, with over a million cases in hospital and nursing home patients every year (15). Increasing duration of catheterization increases the risk of infection (16). Urinary tract infections are the second-most-common infection in noninstitutionalized elderly populations and account for nearly 25% of all infections (9). The financial impact of UTIs is significant, with costs of up to $2 billion per year (17).

While many uncomplicated UTIs in outpatients are diagnosed clinically, the diagnosis of recurrent or complicated UTI is commonly achieved by testing urine specimens for the presence of microorganisms. As a result, urine cultures often make up the largest portion of the workloads of clinical microbiology laboratories (18). The appropriate management of components of the preanalytic phase of urine culture, namely, collection, preservation, and storage of urine specimens, has an important influence
on the generation of meaningful culture results, which ultimately affects patient diagnosis and management (19).

Quality Gap: Factors Associated with the Preanalytic Phase of Urine Culture

The major goal of proper specimen management is to ensure that specimen quality is maintained during collection and transport (20). Urine specimens can easily become contaminated with periurethral, epidermal, perianal, and vaginal flora. This contamination can be reduced with proper attention to techniques for urine collection, transport, preservation, and storage, the major components of the preanalytic phase of urine culture. A Q-Probe study conducted by the College of American Pathologists in 1998 (21) and again in 2008 (22) examined the frequency of urine culture contamination (defined as more than two isolates in quantities greater than 10,000 CFU/ml) and associated facility practices of urine collection and specimen management. Contamination rates of 41.7% (low-performance facilities), 15% (median performers), and 0.8% (high performers) correspond to the 10th, 50th, and 90th percentiles of facilities, respectively (22). Contamination rates had no correlation to collection site, use of collection kits, preservatives, or thermally insulated transport containers. However, contamination rates were substantially affected by postcollection processing, especially refrigeration of the specimen. Also, collection instructions given in the outpatient setting had a statistically significant impact on contamination rates in some cases. Based on the similarities of overall contamination rates between the two Q-Probe studies, the authors concluded that no significant progress in reducing urine culture contamination during the intervening years had been made (22). This may be a reflection of the inherent limitations of the Q-Probe methodology, which is based on one-time quality assessments dependent on the gathering of current data from large numbers of laboratories in order to establish provisional benchmarks for systematic quality improvement efforts. Many of these indicators are based primarily on self-reported surveys rather than on evidence-based scientific study designs and/or adequately specified, standardized, and consistently implemented data collection methods. Nonetheless, it is not cost-effective for laboratories to continue to waste valuable resources on the work-up of contaminated urine cultures (23). Furthermore, inappropriate reporting of contaminated urine cultures by the laboratory can result in patients receiving suboptimal or unnecessary therapy, producing poor patient outcomes and higher cost (18).

To address this important quality gap and its consequences, this research identified and evaluated practices associated with the collection, preservation, and storage of urine specimens for culture and their impact on the accuracy of urine culture microbiology. Rating criteria were used for evaluating these practices. Specific practices examined included collection methods for men, women, children, and infants; preservation of urine samples in boric acid solutions; and the effect of refrigeration on urine storage. The evidence supporting these practices for minimizing contaminated urine cultures and the impact on the accuracy of patient diagnosis were evaluated by applying the LMBP initiative’s systematic review methods for quality improvement practices and by translating the results into evidence-based guidance (24). The methodology has recently been used to evaluate preanalytical practices for reducing blood culture contamination (25) and blood sample hemolysis (26).

A-6 CYCLE FOR SYSTEMATIC REVIEW

The CDC’s LMBP “A-6 Cycle” systematic review methods for evaluating quality improvement practices was used for conducting this review. The methodology, reported in detail elsewhere (24), is derived from previously validated methods. It is designed to assess the results of studies of practice effectiveness that lead to best-practice recommendations that are evidence based. Using this method, a review coordinator (author Mark T. LaRocco) and individuals trained to apply the LMBP methods (authors Alice S. Weissfeld and Elizabeth K. Leibach) conducted the systematic review with guidance from an expert panel. The expert panelists (authors Nancy E. Cornish, Colleen S. Kraft, Vickie Baselski, Robert L. Sautter, Edward J. Peterson, and Debra Rodahl) were chosen based on their breadth of experience and perspective in clinical microbiology and laboratory management. A description of their scientific credentials and professional affiliations can be found in the author biography section. Lastly, the team was supported by a statistician with expertise in evidence review methodologies and meta-analysis (author Jacob Franek). The expert panel reviewed the results of the evidence review and drafted the evidence-based best-practice recommendations. The recommendations were then approved by the LMBP Workgroup, consisting of 13 invited members with broad expertise in laboratory medicine, clinical practice, health services research, and health policy, as well as one ex officio representative from the Centers for Medicare and Medicaid Services. A list of the members of the LMBP Workgroup is provided in Appendix 1.

Review Question, Analytical Framework, and Search Strategy

The review question addressed by this analytical review was as follows: “Are there preanalytic practices related to the collection, preservation, transport, and storage of urine for microbiological culture that improve the diagnosis and management of patients with urinary tract infection?” Components of the preanalytic phase of urine culture were studied in the context of an analytical framework for factors affecting specimen contamination and diagnostic accuracy, depicted in Fig. 1. The population, intervention, comparison, and outcome (PICO) elements are as follows.

- “Population” is any patients who have urine cultures collected.
- “Intervention” is clinical practice.
- “Comparison” is made of:
  - immediate versus delayed processing of urine held at room temperature,
  - immediate versus delayed processing of refrigerated urine or urine preserved in boric acid,
  - midstream clean-catch collection of urine without cleansing versus with cleansing (men and women),
  - midstream clean-catch collection of urine without cleansing versus with cleansing versus collection with a sterile urine bag versus diaper collection for infants and children.
- “Outcomes” are the results of determining the contamination rate and the diagnostic accuracy of urine culture.
Specific practices involving the preanalytic phase of urine culture covered in this evidence-based review were addressed by asking the following eight clinical questions.

1. What is the difference in colony counts when comparing immediate versus delayed processing of fresh urine stored at room temperature after collection?
2. What is the difference in colony counts when comparing immediate versus delayed processing of urine kept refrigerated or preserved in boric acid?
3. What is the difference in contamination rates between midstream urine collected with cleansing versus without cleansing in women being tested for a UTI?
4. What is the diagnostic accuracy of midstream urine collected with or without cleansing compared to bladder catheterization for the diagnosis of UTI in women?
5. What is the difference in contamination rates between midstream urine collection, with or without cleansing, and first-void collection in men?
6. What is the diagnostic accuracy of midstream urine collected, with or without cleansing, compared to that of bladder catheterization or suprapubic aspiration for the diagnosis of UTI in men?
7. What are the differences in contamination rates between midstream collection with cleansing, midstream collection without cleansing, and sterile urine bag or diaper collection in children?
8. What is the diagnostic accuracy of midstream clean-catch, sterile urine bag, or diaper collection compared with that of suprapubic aspiration or catheterization for the diagnosis of UTI in children?

The search for studies of practice effectiveness was conducted to identify those with measurable outcomes collected to the rigor of review requirements. With input from the expert panel and assistance of a research librarian at the Jesse Jones Library at the Texas Medical Center in Houston, TX, a literature search strategy and set of terms were developed. A search of three electronic bibliographic databases (PubMed, SCOPUS, and CINAHL) for English-language articles published between 1965 and 2014 was conducted. In addition, hand searching of bibliographies from relevant information sources was performed. All search results were catalogue and maintained using a Web-based, commercial reference software package (RefWorks; ProQuest LLC, Ann Arbor, MI). Finally, solicitation of unpublished quality improvement studies was attempted by posting requests for data on both the Laboratory Medicine Best Practices website (https://www.cdc.gov/futurelabmedicine/) and two listservs supported by the American Society for Microbiology: clinnicronet (http://www.asm.org/index.php/online-community-groups/listservs) and DivCNNet (http://www.asm.org/division/c/divcnet.htm).

The search contained the following medical subject headings (MESH) and key text words: “urinary tract infections” (MESH) OR UTI (text word) OR urinary tract infect* (text word); “urine/analysis” (major) OR “urine/microbiology” (major) OR “urinalysis” (MESH); “specimen handling” (major); “preservation, biological” (MESH) OR preservation, biological (text word) OR “boric acids” (MESH) OR boric acid (text word) OR boric acid/borate (text word) OR boric acids (text word) OR “refrigeration” (MESH) OR refrigeration (text word) OR preserv* (text word); storage (text word); “time factors” (MESH) OR “transportation” (MESH) OR transport time (text word) OR delay (text word) OR time delay (text word) OR time factor (text word) OR timing (text word); “urine specimen collection” (MESH) OR urine specimen collection (text word) OR “catheters, indwelling” (MESH) OR catheters, indwelling (text word) OR “urinary catheters, continent” (MESH) OR urinary catheters, continent (text word) OR “urinary catheterization” (MESH) OR urinary catheterization (text word) OR “intermittent urethral catheterization” (MESH).
OR intermittent urethral catheterization (text word) OR clean voided (text word) OR midstream (text word) OR bacteriological techniques (MESH) OR bacteriological technique (text word) OR “microbiological techniques” (MESH) OR microbiological technique (text word) OR microbiological techniques (text word).

Titles and abstracts were initially screened by the review coordinator, with assistance from the expert panel when necessary, to select studies for a full review. A study was included if it was considered likely to provide valid and useful information and met the PICO criteria previously discussed. Specifically, these inclusion criteria required that a study (i) address a defined population/definable group of patients, (ii) evaluate a specific intervention/practice included in this review, (iii) describe at least one finding for a relevant outcome measure (percent contamination, diagnostic accuracy) reproducible in comparable settings, and (iv) present results in a format which was useful for statistical analysis. Studies failing to meet the inclusion criteria (not considered to report a relevant practice, did not include a practice of interest, or did not present an outcome measure of interest) were excluded from further review.

Studies that cleared this initial screening were then abstracted and evaluated by the expert panel. For eligible studies, information on study characteristics, interventions, outcome measures, and findings of the study was extracted using a standardized form and assigned a quality rating derived from points awarded for meeting quality criteria. Individual quality ratings were based on four dimensions: study quality, practice effectiveness, defined outcome measure(s), and findings/results. The objective for rating individual study quality was to judge whether sufficient evidence of practice effectiveness was available to support inclusion in an overall body of evidence for evaluation of a best-practice recommendation (that is, a practice likely to be effective in improving one or more outcomes of interest in comparison to other commonly used practices).

The four study quality dimensions were rated separately, with a rating score assigned up to the maximum for a given dimension. The rating scores for all four dimensions were added to reach a single summary score reflecting overall study quality. A total of 10 points were available for each study. Reviewers assigned one of three quality ratings to each study: good (8 to 10 points), fair (5 to 7 points), or poor (4 points or less). Each study was reviewed and rated by two expert panel members to minimize subjectivity and bias. Any study ranked as poor by one reviewer but good by the second reviewer was assigned to a third expert panel member for resolution. More detail on the rating process of individual studies can be found elsewhere (24–26). Studies that did not meet a study quality rating of fair or good were excluded from further consideration. Data from published studies that passed a full review were transformed to a standardized, common metric according to LMBP methods (24). Summary data and quality scores for each publication included in this evidence-based review can be found in Appendix 3 below.

The study quality ratings and results from the individual studies for each clinical question were aggregated into bodies of evidence. The consistency of effects and patterns of effects across studies and the rating of overall strength of the body of evidence (high, moderate, low, suggestive, and insufficient) were based on both qualitative and quantitative analyses. Estimates of effect and the strength of the body of evidence were then used to translate results into one of three evidence-based recommendations (recommend, no recommendation for or against, recommend against). The ratings criteria are described in greater detail elsewhere (24).

While recommendations are based on the entire body of evidence, meta-analyses to generate summary estimates of effect were undertaken for outcomes that provided sufficient data for measurements of diagnostic accuracy and contamination, i.e., proportions of specimens containing periurethral, perianal, epidermal, or vaginal flora. For the outcome of contamination proportion, summary odds ratios were calculated using Mantel-Haenszel methods in a random-effects model performed using Review Manager (RevMan) software version 5.0 (2008; The Nordic Cochrane Centre, The Cochrane Collaboration, Copenhagen, DK). A contamination event was defined according to how individual studies defined contamination because definitions varied between studies. Wherever possible, contamination proportions were determined for the entire test population rather than a subset population (such as only among those individuals that tested negative for urinary tract infection). The I² statistic, which describes the percentage of variability in effects estimates due to statistical heterogeneity rather than sampling error, was used to assess between-study heterogeneity. For the outcomes of diagnostic accuracy, it was planned that point estimates of sensitivity and specificity would be summarized using the bivariate model when similar cutoff points were used; however, all models failed to converge due to a too-small number of study or sample sizes. Similarly, hierarchical summary receiver operator characteristic curves (HSROC) could not be generated because these models too failed to converge. Solutions for failure of convergence, including removing individual studies, were explored but did not improve convergence. Meta-analysis of diagnostic accuracy outcomes and curve fitting were not pursued further given the limitations of univariate methods. All work on summarizing diagnostic accuracy outcomes was performed using SAS software version 9.2 (2008; SAS Institute Inc., Cary, NC, USA) and the MetaDAS macro, version 1.3 (27). Significant growth (i.e., a positive sample) was defined according to how each individual study defined significant growth because cutoff points tended to vary among studies. All other growth, including contamination and no growth, were considered nonsignificant growth (i.e., a negative sample), as this most closely reflects actual clinical practice. Two-by-two tables were used to determine sensitivity and specificity, and exact 95% confidence intervals were calculated.

**Search Results**

Search results produced 5,092 unique documents that were initially screened for eligibility to contribute to evidence of effectiveness for practices defined by the eight clinical questions posed (storage and preservation of urine, collection of urine from women, collection of urine from men, and collection of urine from infants and children). There was no response to requests for unpublished data. The reduction of studies through the screening process is detailed in Fig. 2. Initial screening for topic relevance eliminated 4,917 studies. From the remaining 171 studies, 124 were eliminated for not meeting...
the inclusion criteria (i.e., having elements potentially relevant to at least one topic area review question, reporting practices that are in use and available for adoption, reporting practices reproducible in other comparable settings, and addressing a defined population/definable group of patients). Forty-seven studies met the criteria for inclusion and were subjected to full abstraction and quality scoring. After an additional 12 studies were excluded because of insufficient quality scores, the remaining 35 were included in the statistical analysis: 10 studies on storage and preservation, 8 studies on collection from women, 3 studies on collection from men, and 14 studies on collection from infants and children.

**STORAGE AND PRESERVATION OF URINE**

Summary information on the 10 published studies comprising the body of evidence for the clinical questions on the storage and preservation of urine is presented in Tables 1 and 2. The publication dates for these studies range from 1969 (28) to 1999 (29). All studies were given a “fair” quality rating. Three studies examined the effect of prolonged storage of clean-catch

* BA, boric acid; GBF, glycerol-boric acid-sodium formate; SBF, sorbitol-boric acid-sodium formate; SG, significant growth; NSG, nonsignificant growth.
urine at room temperature by culturing samples of urine immediately upon receipt and then again after 2 h and 4 h (30), after 4 h, 24 h, and 48 h (31), or after 24 h and 72 h (28) of storage at room temperature. Nine studies tested the effect of preserving urine in boric acid for 24 h on colony counts and compared the results with the results of immediate culture. Several different boric acid formulations were used, including boric acid alone (29, 31, 32), glycerol-boric acid-sodium formate (32–37), and sorbitol-boric acid-sodium formate (32, 37). The length of delay of culture while samples were preserved in boric acid was assessed at various time points across studies, but 24 h was chosen for analysis as it was the most common endpoint. Three studies examined the effect of 24-h refrigeration of urine samples on changes in colony counts from those of immediate culture (33, 35, 37). The majority of studies used clean-catch midstream urine samples, although collection methods were undefined in five studies (30, 32, 34, 37, 38). Growth was defined as either “significant” or “nonsignificant.” The definitions of significant growth varied among studies, but in general, a threshold of >10^5 CFU/ml of one or two species of bacteria was used.

**Body-of-Evidence Qualitative Analysis**

The difference in colony counts when immediate and delayed processing of urine specimens stored at room temperature were compared is shown in Table 3. Data from three observational studies (28, 30, 31) found a moderate increase (approximately 10%) in colony counts after 4 h of storage at room temperature and a large increase (>135%) in colony counts after storage for 24 h or more. The effect of delayed culture on urine specimens kept refrigerated or preserved showed similar results. Five studies (31, 32, 34, 37, 38) showed that urine samples preserved in boric acid solutions for 24 h (Table 5) or refrigerated for 24 h (Table 6) had only minor changes in the numbers of cultures with either significant or nonsignificant growth.

These data suggest that both boric acid and refrigeration adequately preserve urine specimens prior to their processing for up to 24 h. Furthermore, the results suggest that urine held at room temperature for more than 4 h should not be processed due to overgrowth of both clinically significant and contaminating microorganisms. Based on statistical analysis of the data, however, the overall strength of this body of evidence was rated as low.

**COLLECTION OF URINE FROM WOMEN**

Summary information on the eight published studies comprising the body of evidence for the clinical questions on contamination rates and the diagnostic accuracy of midstream urine collection from adult females is presented in Tables 7 and 8. Three studies (39–41) were given a quality rating of “good,” and five studies (38, 42–45) were rated as “fair.” Five studies (38–40, 42, 43) examined the impact of perineal cleansing on contamination and are summarized in Table 7. Patient settings included a clinic for adolescents (38), a general practice (38), an antenatal ambulatory-care clinic (39, 43), and a health center for teenagers (40). Definitions of contamination varied among studies and included any growth of normal vaginal flora and/or small quantities (<2,000 CFU/ml) of pathogenic bacteria (38), the presence of epithelial cells (42), mixed growth in quantities of >10^5 CFU/ml (39) or at any quantity (43), and growth of any nonpathogen or pathogen in quantities of <10^5 CFU/ml (43) or <10^6 CFU/ml (40).

Three studies (41, 44, 45) examined the diagnostic accuracy of midstream urine collection with or without cleansing, with straight urinary catheterization as the reference standard (Table 8). Patient populations in these studies included women presenting to an emergency department (41) or ambulatory clinic (44) or admitted to a general medical ward (45). In two studies (43, 44), each patient had urine collected by midstream collection with cleansing, followed by a second collection by urinary catheterization. In the third study (46), no cleansing was performed prior to midstream collection.

**Body-of-Evidence Qualitative Analysis**

The evidence examining the impact of perineal cleansing on contamination of midstream urine specimens collected from females is depicted in Fig. 3. Data from four observational studies (38, 40, 42, 43) and one randomized control trial (39) found no difference upon receipt versus after a 24-h delay with refrigeration (Table 4). Colony counts in urine samples either refrigerated or chemically preserved showed similar results. Five studies (31, 32, 34, 37, 38) showed that urine samples preserved in boric acid solutions for 24 h (Table 5) or refrigerated for 24 h (Table 6) had only minor changes in the numbers of cultures with either significant or nonsignificant growth.

in the odds of contamination between midstream urine specimens collected with or without cleansing. The overall strength of this evidence was rated as high. The diagnostic accuracy of midstream urine collection with or without cleansing is shown in Table 9. Using catheterization as the reference standard, midstream collection had a sensitivity of 98 to 100% and a specificity of 95 to 100%. However, the overall strength of this body of evidence was rated as low.

**COLLECTION OF URINE FROM MEN**

Summary information on the three published studies comprising the body of evidence for the clinical questions on contamination and diagnostic accuracy of midstream urine collection from adult males is presented in Tables 10 and 11. One study (46) was given a quality rating of "good," and two studies (47, 48) were rated as "fair." Two studies (46, 47) examined contamination in midstream clean-cath specimens compared to that in first-void collection specimens (Table 10). Patients in both studies were either ambulatory or hospitalized men with symptoms of urinary tract infection being seen at a VA Medical Center. In the first study (46), men had a first-void and/or midstream urine sample collected, but only half of the patients were asked to wash their glans penis prior to collection. In the second study (47), urine specimens from men were obtained by midstream clean-cath collection, first-void collection, straight catheterization, and suprapubic bladder aspiration, with 7 men being sampled more than once. Contamination was defined as either the growth of >10^3 CFU/ml of two or more colony types (46) or any growth of three or more microbial species (47). For the meta-analysis, only those samples obtained via midstream clean-cath collection and first-void collection without cleansing were compared.

Two studies (47, 48) examined the diagnostic accuracy of midstream urine collection from men using either straight catheterization or suprapubic aspiration as the reference standard (Table 11). One study (47) compared midstream clean-cath specimens to those collected by suprapubic aspiration or straight catheterization in a group of hospitalized or ambulatory men, while the second study (48) compared midstream clean-cath specimens to specimens collected by suprapubic aspiration in a group of patients with spinal cord injury without indwelling catheters. Significant growth in one study (47) was defined as ≥10^4 CFU/ml of a single or predominant species for midstream clean-cath specimens or ≥10^3 CFU/ml for specimens collected by straight catheterization or suprapubic aspiration. Significant growth in the second study (48) was defined as any growth of ≥10^3 CFU/ml for either collection method.

**Body-of-Evidence Qualitative Analysis**

The evidence comparing levels of contamination after midstream urine collection and uncleaned first-void collection is shown in Fig. 4A. Summary data from both studies (46, 47) found a large (77%) reduction in the odds of contamination in favor of midstream clean-cath over first-void specimens. The strength of this evidence was rated as high. Only one study (46) compared midstream collection with cleansing to midstream collection without cleansing (Fig. 4B). Results showed no difference in contamination between the two methods of collection. However, imprecision was largely due to the small event size. The diagnostic accuracy of midstream urine collection from men, with straight catheterization or suprapubic aspiration used as the reference standard, is shown in Table 12. Data for both studies found high diagnostic sensitivity (82 to 100%) and specificity (95 to 100%).

and specificity (92 to 100%) for midstream clean-catch collection. However, the overall strength of this body of evidence was rated as low.

COLLECTION OF URINE FROM CHILDREN

Summary information on the 14 published studies comprising the body of evidence for the clinical questions on contamination rates and the diagnostic accuracy of midstream urine collection from children is presented in Tables 13 and 14. Four studies (49–52) were given a quality rating of “good,” and 10 studies (53–62) were rated as “fair.” Six studies (49, 50, 53–56) compared differences in contamination rates in urine collected by midstream collection (with or without cleansing), collected with a sterile urine bag, or collected from diapers (Table 13). Patients studied ranged in age from 1 month to 18 years. Definitions of contamination varied among studies and included mixed growth in any concentration (54), mixed growth in any concentration or any growth of <10^5 CFU/ml (49–51), and mixed growth at a concentration of >10^5 CFU/ml (56); any specimen interpreted as contaminated by the clinical microbiology laboratory was also included (53).

Eight studies (51, 52, 57–62) examined the accuracy of midstream clean-catch, sterile urine bag, or diaper collection, with suprapubic aspiration or straight catheterization used as the reference standard for diagnosing urinary tract infections in children (Table 14). Patient age ranged from 0 to 10 years. Definitions of significant growth varied across studies, particularly for the reference standards. All studies except one defined significant growth for midstream clean-catch, sterile urine bag, or diaper collection as ≥10^5 CFU/ml. The remaining study (52) defined significant growth by sterile urine bag collection as “pure growth.” Significant growth for suprapubic aspiration or straight catheterization

FIG 3 Difference in contamination levels between midstream urine collected with cleansing (MSCC) versus without cleansing (MS) in women being tested for urinary tract infection. M–H, Mantel-Haenszel statistic; 95% CI, 95% confidence interval.
was defined as any growth in one study (51), growth of $\geq 10^2$ CFU/ml in one study (59), growth of $\geq 10^3$ CFU/ml in one study (62), growth of $\geq 10^4$ CFU/ml in three studies (57, 60, 61), and “pure growth” in one study (52). In one study (58), the definition of significant growth was unclear.

**Body-of-Evidence Qualitative Analysis**

The evidence comparing contamination rates for midstream urine collection with cleansing, midstream collection without cleansing, sterile urine bag collection, and diaper collection is shown in Fig. 5. Data obtained from five observational studies (49, 53–56) and one cluster-randomized controlled trial (50) found larger reductions (68 to 73%) in the odds of contamination for specimens obtained by midstream collection with cleansing than for specimens obtained by the other methods of collection. Data from three observational studies (49, 54, 55) found no significant differences in the odds of contamination between specimens collected with sterile urine bags and specimens taken from diapers. This body of evidence was rated as high.

The accuracy of results for midstream clean-catch urine specimens, sterile urine bag specimens, or diaper specimens, with straight catheterization or suprapubic aspiration used as the reference standard for the diagnosis of urinary tract infection in children, is shown in Fig. 6. Data from eight observational studies showed varied results. The inability to meta-analyze the point estimates of sensitivity and specificity due to small sample and study sizes, together with heterogeneity in positivity thresholds, made interpretation difficult. Similarly, HSROC curves could not be generated, and thus it is unclear which method of noninvasive urine collection is most accurate for the diagnosis of urinary tract infection in children.

**ADDITIONAL CONSIDERATIONS**

This section addresses additional considerations for evaluating preanalytical practices associated with urine cultures and the impact of these practices on contamination and diagnostic accuracy.

**Clinical Applicability**

The studies included in this review reported collection, storage, and preservation of urine samples through commonly used methods for both children and adults in both inpatient and outpatient settings; results are therefore likely to apply to other health care environments. Many of the methods for collection, storage, and preservation are widely recommended (18, 63) and are typically used in most hospitals, outpatient clinics, and clinical microbiology laboratories today (21, 22). The focus of this review, however, is largely on clean-catch midstream urine collection because this method remains the most commonly used in most patient populations and settings (18). This is primarily due to its noninvasiveness; i.e., it has no risk of producing iatrogenic infection, despite the paucity of data supporting its use as a standard (63).

Controversy remains among clinical microbiologists and infectious disease physicians about the most accurate means for diagnosing urinary tract infection in children.

MSCC, midstream clean-catch collection; UFV, first-void urine collection without cleansing; SPA, suprapubic aspiration; CATH, urethral catheterization; SG, significant growth; NSG, nonsignificant growth.

A recent collaboration between the American Society for Microbiology (ASM) and the Infectious Disease Societies of America (IDSA), designed to assist physicians in the appropriate use of laboratory tests for infectious diseases, addressed methods of specimen collection, as well as guidelines for testing patients for urinary tract infections (64). A recommendation was made for collection of urine in a manner to minimize contamination and included midstream collection with cleansing and immediate refrigeration of samples upon collection, although the lack of supporting data was cited (64).

In applying the findings of this review, a strength assessment of the overall body of evidence should be weighted by the quality of findings from individual reports most closely resembling populations and settings of particular interest. For instance, an overall body-of-evidence quality rating may decrease because of the aggregate number of included studies omitting study parameters of little applicability to a particular clinical setting. Researchers may take guidance, with a higher degree of confidence than the overall quality rating might indicate, from individual included studies of high or moderate strength which address specific clinical populations or settings directly comparable to their research interests. The conduct of evidence-based practice would guide clinicians to assess both the quality and the “goodness of fit” of studies relevant to their own particular questions before applying findings in support of their decisions.

This review has directed attention to the need for reexamination of preanalytic factors affecting urine culture. A great number of studies have examined the effects of different methods of specimen collection on the yield of urine culture, but many methodologic issues remain unresolved. The use of midstream clean-catch collection with cleansing is recommended as the preferred method for collection of urine samples for culture, as it is more likely to yield a pure culture of pathogenic bacteria than alternative methods (64).
of the studies covered in the review predate the regionalization and other significant restructuring of the delivery of microbiological services in the United States, which portend increased variation in collection, storage, and preservation methods. More studies are needed to support recommendations for specific populations, e.g., nursing facility residents needing skilled care. Important also is the growing need for documentation of health outcomes and cost-effectiveness of current practices through the implementation of well-designed, system-wide quality improvement studies. Of equal importance is the need to expand (and

communicate) the literature on diagnostic testing algorithms to include nonanalytic variables, such as those measured in the included studies reported here. This systematic review provides a current and substantial literature base from which to begin investigations not only to address these gaps in current knowledge related to the effects of preanalytic factors on urine culture but also to validate these best-practice recommendations in additional settings and populations.

**Associated Harms**

Methods of collecting, storing, and preserving urine specimens for the diagnosis of urinary tract infections have a critical influence on culture results. Poorly collected or preserved specimens can become easily contaminated with perineal, vaginal, and periurethral flora, which can inhibit or obscure the presence of true urinary tract pathogens. Conversely, the use of high concentrations of boric acid as a preservative has been known to inhibit urinary pathogens such as *Escherichia coli* and *Klebsiella pneumoniae* (65).

Midstream urine collection may be the preferred choice for collection for most patients; however, there are patient populations and clinical scenarios where a more invasive method of collection is preferred (63). All of these issues can produce incorrect culture results, misdiagnosis, especially in asymptomatic patients, poor patient management, including the use of inappropriate or ineffective antibiotics, and potentially more complicated urinary tract infection in the long term (2, 3).

**Additional Benefits**

Urine specimens that are appropriately collected, transported, stored, and preserved benefit patients by producing more-accurate culture results. In addition, such practices can provide benefit to the laboratory by allowing technologists to focus on the work-up of clinically significant pathogens rather than the growth of contaminants. Urine cultures are often a major component of the typical clinical microbiology workload (18); therefore, minimizing the processing of poor-quality urine specimens can allow...
the laboratory to focus its resources in a more cost-effective manner (22).

Economic Evaluation

Proper attention to the preanalytic phase of urine cultures should decrease the number of contaminated urine specimens processed by the laboratory. It may also decrease the time it takes for microorganism identification and susceptibility testing of pathogens in infected patients by reducing the number of recollected specimens. Both of these scenarios would likely reduce health care costs for both patients and institutions by reducing the time to appropriate targeted therapy and by making more-effective use of laboratory and hospital resources. However, no economic evaluation analyses were found for the studies covered in this review.

Feasibility of Implementation

The methods of specimen collection and handling covered in this review are feasible in all settings and patient populations and are, in fact, commonly used in most medical environments today. There are data showing the benefit of either refrigerating or chemically preserving urine samples that are not immediately processed (28–37). Furthermore, midstream urine collection, with or without cleansing, is common practice for most clinical settings and patient populations (38–62). For facilities that have historically paid little attention to the preanalytic aspects of urine culture, there may be some resistance on the part of patients and staff that is typically associated with quality improvement initiatives. Appropriate education regarding the proper collection of urine specimens may be needed for both patients and health care workers. The additional costs associated with chemical preservatives, such as boric acid, would also need to be budgeted and justified.

Future Research Needs

The findings of this systematic review highlight the lack of recent high-quality studies that evaluate components of the preanalytical phase of urine culture. For example, the relative paucity of rigorous studies evaluating methods of storage and chemical preservation of urine specimens is troublesome considering the widespread use of these practices in many laboratories and a general consensus among microbiologists as to their benefit. A large number of the studies suffered from small sample sizes, limiting the precision of the results and reducing the likelihood that findings are applicable across a larger population. Studies also used various or unclear definitions of contamination or positivity thresholds, making meta-analysis or qualitative summary analysis problematic. Studies further suffered from missing data. For example, most studies were cross-sectional or otherwise observational (without randomization) in design, but many, particularly those retrospective in nature, did not obtain or report the results of samples from all patients obtained by all collection methods under study. These inconsistencies lead to significantly uneven comparison groups in some cases.

Future studies should strive for statistically sufficient sample sizes, use common and clearly defined definitions of contamination and thresholds for positivity, and report accuracy results across several common positivity thresholds to aid subsequent meta-analysis. An example is the number of positive/negative samples calculated if reviewers use a threshold of \( >10^4 \) versus \( >10^5 \) CFU per ml of urine. Studies should also be more rigorous in design, include more randomized controlled trials, and ensure paired sampling when possible in prospective or cross-sectional studies. Moreover, for all methods under evaluation, patients should have urine collected within a reasonable time frame, and the time delay between collection and culture should be clearly reported.

Finally, future studies should strive to obtain data on down-
stream patient-centered outcomes as influenced by different methods of collection, preservation, or storage of urine that are under evaluation. This broader measurement pool includes system-oriented outcomes, such as time to targeted therapy, cost of antibiotic use, number of UTI discharge diagnoses, or number of _Clostridium difficile_ cases avoided, such that the direct or indirect impact of implementing a particular preanalytic practice can be measured at the patient and organizational level. Information provided in Appendix 2 can be used as a guide to organize and plan studies as well as collect data for any quality improvement project that examines preanalytical practices associated with urine cultures.

**Limitations**

The LMBP systematic review method is compatible with other standards of practice for systematic reviews (24) but includes some unique elements, such as the rating of study quality. Rating study quality is based on attributes such as facility description, study setting and design, practice description, outcome measures, and results. How studies are ultimately considered for inclusion in the review depends on consensus assessments that may be influenced by such things as a rater’s professional background and experience. Indeed, several on-topic studies were excluded because of limitations identified during quality evaluation, mostly related to poor reporting of important study, practice, or outcome details. This is likely somewhat explained by the publication dates of many of the studies, with several of both the excluded and included studies having been published in the late 1960s. As is the case with most systematic reviews, attempts were made to limit publication bias by soliciting unpublished data; however, no unpublished data were submitted. Moreover, restricting the review to English-language studies may also introduce bias.

Outside the limitations of the review process, there were a number of limitations in this review that affected the ability to draw firm conclusions and make recommendations. Most of these limitations were addressed above in the context of future research, but additional limitations will be discussed here. The study settings varied across included studies. Both inpatient and outpatient settings were included, and the specific setting examined in each study—emergency department, adolescent clinic, obstetric clinic, etc.—may not be generalizable to other settings. Some settings may be better equipped to perform certain collection methods or to educate patients or parents on how to perform certain collection methods. Similarly, the patient populations under study varied. Some studies included healthy asymptomatic patients, while others included patients with more-severe conditions, such as spinal cord injury patients. This too might affect the generalizability of results. Within the body of evidence for children, studies often included patients ranging in age from 0 to 16 years. Unfortunately, there were not enough data available to properly stratify children, such as infants, into smaller age groups, and because of this, results may not be generalizable to patients of a specific age. Finally, as discussed above, an important limitation was the variability in positivity thresholds and definitions of contamination used across studies. Although several guidelines have been developed to address definitions of significant bacteriuria for culture (18, 63, 66–68), these guidelines are not always consistent, and this lack of consistency is reflected in the studies and results reported in this review.

**CONCLUSIONS AND RECOMMENDATIONS**

A summary of the findings of this evidence-based review of urine culture preanalytics can be found in Table 15. Conclusions are categorized as “recommended,” “not recommended,” or “no recommendation for or against” and refer to studies of urine collected by noninvasive methods:

1. No recommendation for or against is made for delayed processing of urine that is stored at room temperature, refrigeration vs boric acid. This issue was not addressed in the review.

2. Midstream urine collection from women with cleansing is recommended due to high body of evidence strength and few limitations. However, it is not clearly superior to other collection methods.

3. Midstream urine collection from women without cleansing is recommended due to high body of evidence strength. However, it is not clearly superior to other collection methods.

4. Midstream urine collection from women vs collection by straight catheterization is recommended due to high body of evidence strength. However, it is not clearly superior to other collection methods.

5. Midstream urine collection from men with cleansing is recommended due to high body of evidence strength. However, it is not clearly superior to other collection methods.

6. Midstream urine collection from men without cleansing is recommended due to high body of evidence strength. However, it is not clearly superior to other collection methods.

7. First-void urine collection from men is recommended due to high body of evidence strength. However, it is not clearly superior to other collection methods.

8. Midstream urine collection from men vs collection by straight catheterization or suprapubic aspiration is recommended due to high body of evidence strength. However, it is not clearly superior to other collection methods.

9. Midstream urine collection from children with cleansing is recommended due to high body of evidence strength. However, it is not clearly superior to other collection methods.

10. Midstream urine collection from children without cleansing is recommended due to high body of evidence strength. However, it is not clearly superior to other collection methods.

11. Urine collection from children with sterile urine bags and/or from diapers is recommended due to high body of evidence strength. However, it is not clearly superior to other collection methods.

12. Midstream urine collection from children vs collection by straight catheterization or suprapubic aspiration is recommended due to high body of evidence strength. However, it is not clearly superior to other collection methods.

</table>
erated, or preserved in boric acid due to insufficient evidence. Data from nine studies receiving a “fair” quality rating suggest that both refrigeration and boric acid adequately preserve urine specimens for up to 24 hours prior to their being processed. Furthermore, data from three studies receiving a “fair” quality rating suggest that urine held at room temperature for more than 4 hours should not be processed due to overgrowth of both clinically significant and contaminating flora. However, because the overall strength of the body of evidence was rated as low, no recommendation for or against can be made due to insufficient evidence. This does not preclude the use of refrigeration or chemical preservatives in clinical practice. It does indicate, however, that more systematic studies evaluating the utility of these measures are needed.

2. If noninvasive collection is being considered for women, midstream collection with cleansing is recommended, but no recommendation for or against is made for midstream collection without cleansing due to insufficient evidence. Data from two studies, including one randomized controlled trial receiving a “good” quality rating and three studies receiving a “fair” quality rating, show that contamination rates are similar between specimens obtained by midstream collection with and without cleansing. The overall strength of this body of evidence was rated as high. However, whether midstream collection can be routinely used in place of straight catheterization is unclear. Data from three studies, two with a quality rating of “fair” and one with a rating of “good,” suggest that clean-catch midstream urine collection is highly accurate for diagnosing urinary tract infections in women; however, because the overall strength of this body of evidence was rated as low, no recommendation for or against can be made.

3. If noninvasive collection is being considered for men, midstream collection with cleansing is recommended and collection of first-void urine is not recommended. No recommendation for or against is made for collection of midstream urine without cleansing due to insufficient evidence. Data from two studies, one with a quality rating of “good” and one with a rating of “fair,” found a large reduction in the level of contamination in specimens obtained by midstream collection with cleansing compared to the level of contamination after collection of first-void urine. This body of evidence was rated as high. Although data from one study rated as “good” quality found no difference in contamination between midstream urine collected with and that collected without cleansing, imprecision was large due to the small event size, and no recommendation can be made as to which method is superior. Whether midstream collection can be used routinely in place of straight catheterization or suprapubic aspiration is unclear. Data from two studies receiving a “fair” quality rating suggest that midstream collection with cleansing is highly accurate for the diagnosis of urinary tract infections in men; however, because the overall strength of the body of evidence was rated as low, no recommendation for or against can be made.

4. If noninvasive collection is being considered for children, midstream collection with cleansing is recommended and collection with sterile urine bags, from diapers, or midstream without cleansing is not recommended. Data from six studies, two with a quality rating of “good” and four rated as “fair,” found large reductions in contamination in midstream clean-catch urine specimens compared to contamination after other noninvasive methods of collection. This body of evidence was rated as high. Whether midstream collection with cleansing can be routinely used in place of catheterization or suprapubic aspiration is unclear. Data from eight studies, two with a quality rating of “good” and six rated as “fair,” suggest that midstream collection with cleansing is accurate for the diagnosis of urinary tract infections in infants and children and that midstream collection with cleansing has higher average accuracy than sterile urine bag collection (data for diaper collection was lacking). However, the overall strength of evidence was low, as multivariate modeling could not be performed; thus, no recommendation for or against can be made due to insufficient evidence.

APPENDIX 1
The members of the Laboratory Medicine Best Practices Workgroup from 2012 to 2014 were as follows: Robert H. Christenson, University of Maryland Medical Center, Baltimore, MD; John Fontanesi, UC—San Diego Medical School, La Jolla, CA; Julie Gayken, Regions Hospital, St. Paul, MN; James Nichols, Vanderbilt University Medical Center, Nashville, TN; Mary Nix, Agency for Healthcare Research and Quality, Rockville, MD; Milenko Tanasijevic, Brigham and Women’s Hospital, Boston, MA; Sharon Geaghan, Stanford, University School of Medicine, Stanford, CA; Christine Litwin, Georgia Health Sciences University, Augusta, GA; Thomas Lorey, Permanente Medical Group Regional Laboratory, Richmond, CA; Bernadette Mazurek Melnyk, The Ohio State University, Columbus, OH; Anton Piskac, Methodist Health System, Omaha, NE; Jennifer Rahmy, St. Mary’s Hospital, Oakbrook Terrace, IL; Christopher Lee Roy, Brigham and Women’s Hospital, Boston, MA; and Melissa Singer (ex officio), Centers for Medicare and Medicaid Services, Baltimore, MD.

APPENDIX 2
LMBP Evaluation of Preanalytic Practices for the Contamination and Diagnostic Accuracy of Urine Cultures

Suggested guidance for future studies. This review identified and rated practices associated with the collection, preservation, and storage of urine specimens for culture and assessed the impact of these preanalytic practices on the diagnostic accuracy of urine culture microbiology. In theory, the design, description, methods, data collection, and analysis for any study should be written and documented so that other investigators can reproduce exactly the same study in their laboratory, with their results validating or verifying those of the original study. The following organizational plan with instructions can be used as a guide for quality improvement project design, implementation, and evaluation of preanalytic practices associated with urine cultures. Figure A1 shows a form for use in collecting data for any QI project that examines preanalytical practices associated with urine cultures.
### Background Information

1. Problem/quality issue description.

A. Practices

i. Collection

   - Midstream clean catch vs. midstream w/o cleansing
   - Midstream clean catch vs. straight catheter/suprapubic aspiration
   - Midstream w/o cleansing vs. straight catheter/suprapubic aspiration
   - Midstream w/o cleansing vs. first void
   - Midstream w/o cleansing vs. diaper collection/sterile urine bag

   Other

ii. Storage and Preservation

   - Refrigeration
   - Boric acid
   - Glycerol boric acid
   - Sorbitol boric acid
   - Stool temperature

---

**Background Information**

1. Problem/quality issue description.

A. Practices and equipment. Describe what preanalytic practices associated with the collection and preservation of urine for culture were studied and exactly how specimens were collected. Include examples of educational material handed to patients or displayed on walls in areas where patients were seen.

   i. Collection. Indicate whether specimens were obtained by midstream clean-catch collection versus midstream collection without cleansing, midstream clean-catch collection versus straight catheter collection and/or suprapubic aspiration, midstream collection without cleansing versus straight catheter collection and/or suprapubic aspiration, midstream collection with or without cleansing versus first-void urine collection, midstream collection with or without cleansing versus diaper collection and/or sterile urine bag collection, or other means.

   ii. Preservation/storage/transport. Include the time from collection of the specimen to the addition of preservative and how long it took the specimen to reach the lab after collection, as well as how long it took from receipt in the lab to setup of culture. Indicate whether boric acid, glycerol boric acid, or sorbitol boric acid was used as a preservative, whether the specimen was stored in a refrigerator or at room temperature, and any other relevant preservation or storage information.

B. Population under study and age ranges. Include physical differences which may affect the collection of the specimen, such as physical disability, the presence of a foreskin in males, the presence of diapers, etc. With infants and neonates, consider tighter age ranges, such as 0 to 2, 2 to 4, etc.

C. Collection personnel. Indicate whether the specimen was collected by a nurse, nurse’s aide, physician, specialized urine collection team, lab technologist or technician, or other staff member.

2. Submitter(s) and organization affiliation.
questions concerning the quality improvement (QI) study, contact information is required.

3. Funding source(s). Refer to the chart in Fig. A1. Check all boxes that apply.

QI Project/Study

4. QI project study design/type. With similar patient populations, describe the methods/approaches used for your project with regard to age, sex, ethnicity, and/or diagnosis to limit bias.
   A. Pre- and postimplementation. Observations are made before and after the implementation of an intervention.
   B. Split implementation design. Indicate whether multiple sites were used to conduct the QI study.
   C. Case-control study. Indicate whether the study compared subjects with a specific outcome of interest (cases) with subjects from the same source population but without that outcome (controls) to examine the association between the outcome and prior exposure (for which there was an intervention).
   D. Cross-sectional associations. Collect information on interventions (past or present) and current health outcomes, i.e., those that are restricted to health states, for a group of people at a particular point in time, to examine associations between the outcomes and exposure to interventions.
   E. Cohort. A defined group of people (the cohort) is followed over time to examine associations between different interventions received and subsequent outcomes.
   F. Randomized assignment. Patients are randomly selected to receive the intervention practice or the comparator practice.
   G. Other study design used in this QI project. Describe the study design selected.

5. Facility description. Provide a complete description of the facility type and the number of beds (or patients if the facility is an outpatient facility).

6. Study setting. Select the unit(s) within the facility where the practice was implemented, e.g., inpatient, outpatient, emergency department, pediatric unit, neonatal intensive care unit, or other.

7. Overall project/study timeframe. Record the start and end dates for the new and usual practices; if pilot testing was conducted, include start/end dates for pilot testing of the new practice. Note that this is not the same as the QI study period but rather the dates during which these practices were being used in the unit(s) in which the study was done. Put “NA” if some dates are not available.

8. Sampling strategy. The sample size is the number of patients/observations used for the usual (current) practice and the alternate practice. Use the largest available sample size at each time of measurement. For results to be reliable, the implemented practice should be the only thing affecting the results. It is the largest sample size available that represents only the results of the usual practice and the largest sample size that represents only the results of the alternate practice. Describe your sample set (tests, patient specimens, patients, or type of patient specimens) and the sample size (example: prior to [usual] practice [15,000 patient specimens tested] and after [alternate] practice [13,200 patient specimens tested]).

Optimally, a power analysis should be performed prior to confirmation of sample size. Statistical power is the probability of concluding that there is a difference when there is, in fact, a difference between your standard method and your new method (i.e., the probability that your study will detect a difference, given that one truly exists). An example of a nomogram for sample size calculation can be found in reference 69.

Statistical power is the probability of concluding that there is a true and significant difference between your comparator and intervention, thus minimizing type I and type II errors (sensitivity and specificity).

For sample description, refer to the following list.

A. Random sampling. Subjects (patients) are selected for study inclusion using a formal random selection process applied to the census.
B. Convenience sampling. Some subset of the census is selected since it is easy to access. For example, using only data from records of patients whom you can easily reach would be a convenience sample.
C. Census sampling. All participants within a specified time period or location are used in census sampling.
D. Other. Describe whether you are using a different sampling method. If you are using anything other than random sampling, convenience sampling, or census sampling, you need a statistician to identify sampling strategy.

QI Practice

9. Describe the original (usual) practice. Describe the original (usual) practice(s) that will be compared to the new practice/policy/technology implemented.
10. Describe the alternate/intervention (new) practice. Describe the new practice/policy/technology, including the characteristics and components for ongoing day-to-day operations.
11. Intervention duration dates (pilot, pre/postintervention, etc.). Record the start and end dates for the pilot testing, usual practice, and new practice. This is the date on which the particular QI project was implemented and the date on which it ended. Note that a pilot test may not have been used in this study. There should be no gaps in the QI project data collection once it begins.
12. Resource requirements/costs. Describe the requirements and costs for starting and sustaining the new practice during the study. If this information is not available, list “not known.” Do not list the cost of the practice that is currently being used to do patient testing.

Outcome Measures

13. Outcome measure(s). Describe how the impact of the practice was measured. Provide the specific outcome(s) and corresponding specifications/definitions used to assess or track the impact of the practices implemented. An example is a description of how urine culture contamination rates were affected or how they had an impact on the diagnostic accuracy of urine culture.
14. Recording method. Describe each method used to collect data and to which practice (usual or new) it refers.

15. Potential sources of bias. Bias is the tendency to produce results that depart systematically from the “true” results. Bias is any nonrandom factor in the conduct of a study that can influence the results of a study.

A. Selection bias. Selection bias occurs when studies are conditioned on (that is, they differentially select for) common effects of the exposure and the outcome. Selection bias occurs after exposure and arises when the associations between exposure and outcome are different for those who participate and those who do not participate in a study (i.e., all those who are theoretically eligible). This bias includes inappropriate selection of controls in a case-control study, different losses to follow-up for groups being compared (attrition bias), incidence/prevalence bias, nonresponse bias, and inclusion or exclusion of specific groups for study.

B. Performance bias. Performance bias includes systematic differences in the types of care provided to participants and protocol deviations. Examples include contamination of the control group with the exposure or intervention, unbalanced provision of additional interventions or cointerventions, a difference in cointerventions, and providers and participants not being adequately blind to the study results.

C. Detection bias. Detection bias includes systematic differences in outcome assessments among groups being compared. Reasons for this bias include misclassification of the exposure, intervention, covariates, or outcomes because of varying definitions, timings, diagnostic thresholds, and memories of an event; assessors not being adequately blind to the study results; and faulty measurement techniques. Erroneous statistical analysis might also affect the validity of effect estimates.

D. Confounding bias. Confounding bias is the presence of systematic differences between baseline characteristics of the groups that arise when patient prognostic characteristics, such as disease severity or comorbidity, influence both treatment source and outcomes. Confounders are the common cause for intervention and exposure; they occur before exposure. Confounding by indication can occur from self-selection of treatments or physician-directed selection of treatments.

E. Reporting bias. Reporting bias is the presence of systematic differences between reported and unreported findings (e.g., differential reporting of outcomes or harms, incomplete reporting of study findings, and potential for bias in reporting through source of funding).

Results/Findings

16. Results/findings as related to study design/outcome measure. For each outcome provided, summarize the results/findings of the study/project related to the practice. Provide the total number of observations (samples) on which the results are based and statistical tests results, if a statistical analysis was performed. Include findings related to cost savings or shortened length of stay, if applicable.

17. Data analysis with regard to statistics. Describe the statistic used to measure the strength of association or the statistical measures of the performance of classification tests (e.g., sensitivity, specificity). Examples are as follows.

A. With first-void urine collection, 10 urine samples are contaminated per 100 urine cultures performed (10% contamination rate).

B. With midstream clean-catch urine collection, 3 urine samples are contaminated per 100 urine cultures performed (3% contamination rate).

C. The odds ratio is 0.28 (3/10/97/90).

18. Data analysis with regard to significance. Describe the tests of significance. Include calculations of the statistical significance of a difference between the usual practice and the alternate practice on the measured outcomes listed in item 14.

19. Barriers to implementation. Describe any outside activities occurring at the same time as the project, such as staff changes or new policy, that may have influenced the results of the project. Describe any barriers that directly impacted the project.

20. Study dates completed or report submitted. Dates should include the date that the study was completed, the date it was reported (and where it was reported), and the date it was submitted to the LMBP initiative.

APPENDIX 3
Refer to Tables A1 to A4 for evidence summaries of results for storage (refrigeration versus room temperature) and boric acid preservation of urine, contamination and diagnostic accuracy of urine collected from women, contamination and diagnostic accuracy of urine collected from men, and contamination and diagnostic accuracy of urine collected from children.

TABLE A1 (Continued)
TABLE A1 (Continued)

| Authors: Lauer et al. (35) | Title: Evaluation of Preservative Fluid for Urine Collected for Culture | Yr: 1979 | Publication: J Clin Microbiol | Affiliations: Division of Infectious Diseases and Clinical Microbiology Laboratory, Departments of Pediatrics and Medicine, University of Colorado Medical Center, Denver, CO | Funding: supported by a grant from Becton, Dickinson | Description: Each specimen was cultured four times on 5% sheep blood agar and MacConkey agar. Biplates by the surface streak technique with a calibrated 0.001-ml platinum loop at the intervals described below. | Description: Urine specimens that grew >10^4 CFU/ml of a potential urinary tract pathogen/ml in pure culture were considered positive. Cultures growing <10^4 CFU/ml or a mixture of organisms were considered negative. Colony counts were recorded as >10^1, 10^1–10^2, or 10^2–10^6 CFU or no growth. | Type of findings: observational findings/effect size: 1. 88 reference cultures grew >10^6 CFU/ml of a single potential urinary tract pathogen. Culture results were comparable after refrigeration or chemical preservation for 24 h; both methods detected 82 of the 88 positive reference cultures (93.2%). The discrepancies mostly consisted of growth of the pathogen in addition to growth of a few Gram-positive urogenital tract contaminants on comparison plates but not in the reference cultures. |
| Authors: Southern and Dickinson | Title: Use of the Becton, Dickinson Urine Culture Tube with the Abbott MS-2 Urine Screening System Yr: 1984 | Publication: Diagn Microbiol Infect Dis Affiliations: Department of Pathology, The University of Texas Health Science Center at Dallas, and Clinical Microbiology Laboratory, Parkland Memorial Hospital, Dallas, TX | Funding: Support provided by Becton, Dickinson | Description: Patients voided urine that was collected in midstream clean-catch fashion in a sterile container. Immediately, a sample of urine was drawn into a Becton, Dickinson urine culture kit tube and another into a sterile screw-cap tube. Both tubes were sent to the laboratory as soon as possible. In transport could not be accomplished within 20 min, the sterile conventional tube was refrigerated. In the laboratory, both tubes were streaked with a calibrated quantitative loop onto eosin-methylene blue agar, Columbia nalidixic acid blood agar, and blood agar. Each tube was also inoculated into an Ampette of the Abbott MS-2 apparatus for purposes of screening for bacteriuria. | Description: All specimens not determined to be positive by the MS-2 within 6 h were reported as negative. The numbers and types of organisms isolated on each plate for each specimen were recorded. If the colony count exceeded 50,000/ml for Gram-positive cocci or 100,000/ml for Gram-negative bacilli (unmixed cultures), then all isolates were identified and antimicrobial susceptibility testing was performed. The Becton, Dickinson tubes were held an additional 24 h at room temp, and a delayed quantitative culture was done for comparison with the original. | Type of findings: comparison findings/effect size: 1. 124 urine specimens were positive in both conventional and Becton, Dickinson tubes. Escherichia coli (n = 72), Klebsiella pneumoniae (n = 20), Enterobacter cloacae (n = 8), Proteus mirabilis (n = 4), group B streptococcus (n = 12), and enterococcus (n = 8) were isolated. 2. Times for detection of positive urine samples were similar for both preserved and unpreserved samples. Delayed cultures had significant numbers of false-positive results. Antibacterial susceptibility results did not appear to be influenced by Becton, Dickinson tube transport. MS-2 cannot adequately discriminate cultures containing <50,000 CFU/ml of urine. Statistical significance/tests: not reported Results/conclusion bias: MS-2 system could not detect colony counts below 10^2 CFU/ml |

| **Authors:** Blake and Doherty (38) | Design: randomized controlled study Facility/setting: academic medical center Time period: 6 June–1 August 2003 Population/sample: Participants selected from an adolescent clinic were assigned to either the standard collection group (n = 25) or the sequential collection group (n = 25). | Participants were assigned to either the standard collection group or the sequential collection group. Standard collection group (n = 25) participants were instructed on the collection of an MISC urine sample. They were told to cleanse their perineum with a towell ette, pass the first part of their urine into the toilet, and collect the next part of their urine in a sterile container. Sequential-collection group (n = 25) participants were instructed not to cleanse their perineum and to collect 2 sequential urine samples by voiding 10 to 20 ml into the first container and the remainder into a second sterile container. Midstream urine specimens from both groups were transported to the laboratory for culture. Duration: 2 mo Training: patient instructions given Staff/other resources: not reported Cost: not reported | Description: perineal flora contamination rate of midstream urine cultures collected with and without perineal cleansing Recording method: questionnaire given to patients | Type of findings: comparison of colony counts
Findings/effect size: 1. No culture grew >10,000 colonies of a pathogenic bacterium. 11 (44%) of the exp1 group samples and 9 (36%) of the control samples grew >10,000 colonies of perinical bacterial flora (chi square = 0.33; P = 0.56). Participants’ previous experience collecting midstream urine was not associated with less bacterial contamination.
2. While the mean rating for comfort with the collection method was higher in the standard collection group than in the sequential-collection group, the mean ratings for ease of collection were not significantly different between groups.
3. A relatively large proportion of cultures showed perineal-flora growth in both the sequential-collection and standard-collection groups, suggesting that perineal cleansing does little to reduce contamination.
Statistical significance/tests: chi-square, Fisher’s exact test, and Spearman correlation were used to compare the groups. Data analyses were performed using SPSS version 12.0 (SPSS Inc. Chicago, IL).
Results/conclusion biases: small sample size, use of asymptomatic patients only |

| **Authors:** Bradbury (42) | Design: individual randomized control study Facility/setting: 5-physician private-practice setting Time period: not reported Population/sample: A total of 316 urine specimens were collected from 158 female patients suspected of having UTIs and from 158 controls. The study group comprised any female aged 16–75 yr who presented with symptoms of frequency and dysuria. The control group comprised the next nonpregnant female attending the surgery with no urinary tract symptoms. The women were randomly allocated to one of the 2 methods of urine collection. Comparator: clean-catch collections Study bias: control group without symptoms of UTI | Those using the cleaning method were instructed to wash their hands and then use the 3 cotton wool swabs provided to cleanse the genital area with soap and water. They were told to part the labia and wipe from front to back 3 times using a clean swab each time. Keeping the labia parted they passed some urine into the toilet and then caught some urine in a sterile container containing 0.4 g of boric acid as a preservative. Participants not using the cleaning method were instructed simply to pass some urine into the toilet, stop and then catch the next urine in a sterile RA container Duration: 16 mo Training: each patient was given written collection instructions Staff/other resources: not reported Cost: not reported | Description: Samples were evaluated by standard microbiological techniques and classified as definite or equivocal infection based on the quantity of microorganisms.
Recording method: routine laboratory reports | Type of findings: comparison of culture results, calculation of contamination rates
Findings/effect size: A total of 316 specimens, 158 from women with symptoms of cystitis and 158 from asymptomatic controls, were examined. No significant differences were found in the numbers of contaminated or unreliable results between the specimens collected with and those collected without preparatory cleansing.
Statistical significance/tests: not reported Results/conclusion biases: none reported |

Total quality rating (10-pt. maximum): 7, fair

### TABLE A2 (Continued)

| Authors: Holiday et al. (39) | Title: Perineal Cleansing and Midstream Urine Specimens in Ambulatory Women | Yr: 1991 | Publication: J. Hosp Infect | Institute of Pathology and Tropical Medicine, Halton, Aylesbury, Bucks, United Kingdom | Funding: not reported | Design: randomized comparison study | Facility-setting: general teaching hospital | Time period: not reported | Population/sample: asymptomatic antenatal patients, randomized to 2 groups of 96 each | Comparator: midstream urine collection after cleansing with sterile saline and sterile gauze | Study bias: lower-than-expected rate of significant bacteriuria | Description: Sterile packs were used for all specimens. Non-cleansing patients were instructed in the use of the pack only. Cleansing patients received the same information but additionally were asked to clean the genital area with sterile gauze swabs soaked in sterile normal saline and used with a single backwards stroke before finally drying the area with another sterile gauze swab. | Duration: not reported | Training: infection control nurse provided training to antenatal nurses; nurses provided detailed instructions to patients | Staff/other resources: nurses and laboratory staff | Cost: not reported | Type of findings: comparison of culture results | Findings/effect size: 1. No significant difference in distributions of colony count results (P > 0.1 by χ²) was found. 2. The only significant difference in microscopic findings (>50 epithelial cells) was found with 12 individuals in the non-cleansing group and 4 in the cleansing group (P = 0.017); no other differences for WBC or RBC were found. | Statistical significance/tests: chi-square test, Fisher’s exact test | Results/conclusion biases: results may apply only to ambulatory antenatal patients |
| Total quality rating (10-pt. maximum): 8, good | Authors: Schlageter et al. (40) | Title: Perineal Cleansing Does Not Reduce Contamination of Urine Samples from Pregnant Adolescents | Yr: 1993 | Publication: Pediatr Infect Dis J | Affiliations: Department of Pediatrics, University of Virginia Health Sciences Center, Charlottesville, VA | Funding: not reported | Design: nonrandomized comparison study | Facility-setting: teen health center/academic medical center | Time period: not reported | Population/sample: convenience sample of 100 pregnant, low-income teens; 10–19 yr; exclusions were patients with UTI or a UT abnormality and patients who had taken antibiotics within 7 days | Comparator: clean-catch urine collection | Study bias: potential selection bias | Description: Each subject gave 2 urine samples during consecutive urinations in 1 routine prenatal visit; the first was by midstream collection, the second by clean-catch collection. Urine samples were refrigerated immediately after collection, plated within 5 h of collection, and cultured by routine microbiological techniques. | Duration: not reported | Training: patients were given verbal instructions by nurses. | Staff/other resources: nursing | Cost: a potential cost savings of $97,560/yr if clean-catch practices were stopped | Total quality rating (10-pt. maximum): 8, good |
| Authors: Schneeberger et al. (43) | Title: Contamination Rates of Three Urine-Sampling Methods To Assess Bacteriuria in Pregnant Women | Yr: 2013 | Publication: Obstet Gynecol | Affiliations: Departments of Epidemiology and Obstetrics and Gynecology, University Medical Center, Groningen, Amsterdam, Netherlands | Funding: not reported | Design: cross-sectional | Facility-setting: outpatient obstetrics clinic | Time period: April 2010–April 2011 | Population/sample: convenience sample of 113 pregnant women who had had 3 different midstream urine samples collected consecutively: first void, midstream without cleansing, and midstream clean-catch. | Comparator: midstream sample used as reference test. | Study bias: sample size too small to detect some differences in collection technique. | Description: 3 methods of collection were compared for differences in Gram stain, leukocyte, esterase and nitrate dip stick, and culture results. | Duration: 12 mo | Training: oral and written sampling instructions were provided to each participant. | Staff/other resources: not reported | Cost: not reported | Type of findings: comparison | Findings/effect size: Mainly low numbers of Gram-positive rods were more likely to be present in Gram stains of midstream samples than in clean-catch samples (77.7% compared with 66.2%; P = 0.022). Morning samples showed more mixed growth than midstream samples (6.2% compared with 0.9%; P = 0.050). No consistency in quantity of contaminants was found in midstream samples compared with morning and clean-catch samples. No differences were found between the other endpoints in all 3 urine samples (P > 0.05). The study could detect an odds ratio of 2.0 for differences in urine-sampling methods with 80% power and 5% significance for most endpoints. | Statistical significance/tests: Fleiss-Cohen’s weighted K statistic, odds ratios, generalized score test | Results/conclusion biases: study not appropriately powered for all measures, nearly all samples were contaminated | (Continued on following page)

**Title:** Urine Sampling in Ambulatory Women: Midstream Clean-Catch versus Catheterization

Yr: 1989

Publication: Ann Emerg Med

Affiliations: Department of Emergency Medicine, Valley Medical Center, Fresno, CA, and Departments of Medicine and Family and Community Medicine, University of California, San Francisco, CA

Funding: supported by a grant from the Medical Research Committee of Valley Medical Center, Fresno, CA

Design: nonrandomized case series

Facility/setting: teaching hospital

Time period: May–November 1986

Population/sample: 105 consecutive women.

Selection criteria included any ambulatory adult woman or legally emancipated female minor who presented to the Emergency Department

Training: Patients received standardized verbal instructions from a nurse on the method of MSCC urine collection.

Staff/other resources: not reported

Cost: not reported

**Description:** Each patient spread her labia, prepped her perineal area by wiping 3% providone-iodine-soaked 4- by 4-in. gauzes in an anterior-to-posterior direction, and spontaneously voided a midstream clean-catch urine sample. Then, the patient was immediately sterilely prepped with providone-iodine and catheterized by a nurse using a Davol single-use female catheterization kit.

Duration: 7 mo

Findings/effect size: Findings were compared by microscopic urinalysis, dipstick urinalysis, and urine culture. Leukocyte esterase and nitrites were reported as positive or negative. WBC were reported as the actual no. per HPF. Microscopic bacteriuria was reported as 0 if absent, 1+ for 1 to 10 bacteria/HPF, 2+ for 10 to 100 bacteria/HPF, 3+ for bacteria that were innumerable but loosely packed in each HPF, and 4+ for bacteria that were innumerable and tightly packed in each HPF. A culture-proven UTI was defined as more than 10,000 colonies of at least a single species/mL of catheterized urine.

Recording method: not reported

Type of findings: comparison

Statistical significance/tests: McNemar’s test, Fischer’s exact test, and power analysis. Two-tailed statistical tests were performed.

Results/conclusion biases: Findings were limited to ambulatory women who have 1 or more symptoms compatible with a UTI and were specifically instructed in the proper technique of MSCC urine sampling.

**Title:** Reliability of Clean-Voided Midstream Urine Specimens for the Diagnosis of Significant Bacteriuria in the Female Patient

Yr: 1968

Publication: Can Med Assoc J

Affiliations: Renal Laboratory and Renal Clinic Montreal School of Medicine; Department of Bacteriology, Hotel-Dieu Hospital, Montreal, Canada

Funding: supported in part by a grant from Hoffman La Roche Limited

Design: cross-sectional

Facility/setting: teaching hospital

Time period: not reported

Population/sample: 3 groups of patients were studied. Group 1 consisted of 53 healthy student nurses (aged 18 to 23 yr; mean, 19 yr) having a first morning cleanly voided midstream specimen collected. Group 2 consisted of 29 female patients admitted to a general medical female ward service (aged 21 to 53 yr; mean, 42 yr) with both clean-void and catheterized urine specimens collected at the same time. Group 3 consisted of 27 female patients (aged 24 to 54 yr; mean, 43 yr) admitted to either a semiprivate or general medical ward. Both cleanly voided and catheterized specimens were collected at the same time.

Comparator: not reported

Cost: not reported

**Description:** All specimens were collected in the same room by the same 2 nurses. Both the nurses and patients wore sterile rubber gloves during the entire procedure of urine collection. The perineum was carefully scrubbed with green soap for 2 to 3 min. The labia majora were then separated, and the vulva was washed with green soap, with a fresh cotton swab used after each time period. The same maneuver was repeated with an aqueous solution of Zephran (benzalkonium; 1:1,000). The subjects were then instructed to void after separating the labia majora. After the stream was well started, a sterile screw-cap jar was placed into the path of the stream and a small sample of urine collected. Subjects from whom paired specimens were obtained were told to stop voiding as soon as the cleanly voided specimen was obtained. A sterile rubber French no. 8 catheter lubricated with a small amt of sterile lubricant was then inserted into the urethra, and a final specimen was collected in another screw-cap jar. The specimens were taken immediately to the laboratory, where they were processed for bacterial counts, routine bacterial identification, and Gram staining.

Duration: not reported

Findings/effect size: Of the 105 patients, 42 (40%) had a culture-proven UTI. The concordance rates between MSCC and CATH results for bacteria cultures, nitrites, leukocyte esterase, significant microscopic bacteriuria, and pyuria were 96%, 94%, 93%, 90%, and 90%, respectively. There were no statistically significant differences between MSCC and catheterized specimens for sensitivities, specificities, or positive or negative predictive values for any urinalysis variable (leukocyte esterase, nitrites, significant microscopic bacteriuria, or pyuria).

Recording method: not reported

Type of findings: comparative colony counts

Statistical significance/tests: not reported

Results/conclusion biases: not reported

<td>Authors: Lipsky et al. (46)</td>
<td>Design; group randomized control study</td>
<td>Description: Subjects were directed to collect paired voided urine specimens for culture. Those whose Social Security numbers ended in an even digit were instructed to cleanse their glans penis with a povidone-iodine pad prior to voiding. Persons with odd Social Security numbers served as noncleansed control subjects. Patients in both groups collected 10 to 20 ml of “initial” and “midstream” specimens by passing the first part of the voided urine into a sterile cup, discarding the next 100 to 200 ml of urine into the urinal, and then collecting a second aliquot of urine in another sterile container. All specimens were immediately refrigerated at 4°C and delivered within 4 h to the clinical microbiology laboratory for Gram staining and semiquantitative culture. Organisms were identified using standardized techniques. Nonhemolytic streptococci were characterized as viridans streptococci or enterococci. All other organisms were identified to the species level. Duration: 7 mo</td>
<td>Description: A “positive” culture was defined as one with growth of 10,000 or more CFU/ml of a single or predominant organism. Specimens growing 1,000 CFU/ml of a single or predominant organism were called “indeterminate.” Those with 1,000 or more CFU/ml with 2 or more colonial types and with no predominant organism were defined as “contaminated.” Specimens growing less than 1,000 CFU/ml were considered “negative.”</td>
<td>Type of findings: comparison</td>
</tr>
<tr>
<td></td>
<td>Facility/setting: urology clinic, VA medical center</td>
<td>Recording method: routine microbiological techniques; cultured by standard microbiological techniques; urine leukocytes were quantitated with a hemacytometer. Plates were examined after incubation for 18–24 h. Isolates from plates with fewer than 3 different colonial types were identified to the species level. Urine leukocytes were quantitated (in cells/mm³) of uncentrifuged urine) in a hemacytometer. Sensitivity, specificity, positive predictive value, and negative predictive value were calculated for results of culture of the uncleansed first-void and clean-catch midstream-void specimens, with bladder specimens used as the reference standard.</td>
<td>Results/effect size: The rates of true bacteriuria and contamination were compared in the various collection technique subgroups. Neither the bacteriuria nor contamination rates were significantly different (P &gt; 0.05) in circumcised and uncircumcised patients, or in those who cleansed their meatus and those who did not. Contamination but not bacteriuria rates were higher in initial than in midstream specimens.</td>

Authors: Lipsky et al. (47) | Design; observational study Facility/setting: VA medical center | Description: Specimens were collected in the following order: suprapubic aspiration (10 ml), uncontaminated first void (the first 10 ml was voided without prior cleansing of the urethral meatus), clean-catch midstream-void (10 ml) was voided after cleansing the urethral meatus with povidone-iodine and voiding ~100 ml), and urethral catherization (10 ml). At least 1 bladder (suprapubic aspiration or urethral catherization) and 1 voided (uncleansed first void or clean-catch midstream-void) specimen were collected from every subject. Duration: not reported | Description: Specimens were cultured by standard microbiological techniques; urine leukocytes were quantitated with a hemacytometer. Plates were examined after incubation for 18–24 h. Isolates from plates with fewer than 3 different colonial types were identified to the species level. Urine leukocytes were quantitated (in cells/mm³) of uncentrifuged urine) in a hemacytometer. Sensitivity, specificity, positive predictive value, and negative predictive value were calculated for results of culture of the uncleansed first-void and clean-catch midstream-void specimens, with bladder specimens used as the reference standard. | Type of findings: comparison |
| | Time period: not reported Population/sample: 66 ambulatory or hospitalized male patients who had acute dysuria or other irritative genitourinary symptoms, were known to have bacteriuria, or were scheduled for a urologic procedure. Individuals were excluded because of an inability to void at will, use of any type of internal or external device for urine collection, massive obesity, previous lower abdominal surgery or radiation therapy, known or suspected bladder neoplasm, or any coagulation disorder. Comparator: urine collected by suprapubic aspiration Study bias: subjects were not randomly selected. | Training: not reported Staff/other resources: not reported Cost: not reported | Results/effect size: Bladder bacteriuria was found in 36 of 76 sets of specimens from 66 individuals. Culture results of bladder specimens showed excellent agreement with the standard clean-catch midstream-void and uncleansed first-void specimens. The criterion for clean-catch midstream-void specimens that best differentiated sterile from infected bladder urine was the growth of >1,000 CFU/ml of 1 predominant species. Uncleansed first-void specimens were equally sensitive (0.97) but less specific (0.91–0.92) in detection of bacteriuria. Pyuria (>1,000 leukocytes/mm³) and irritative genitourinary symptoms showed modest correlations with bladder bacteriuria. | |

#### Bibliographic information
- **Total quality rating (10-pt. maximum):** 6, fair
- **Total for study (2-pt. maximum):** 2 (not a controlled study)
- **Total for practice (2-pt. maximum):** 1 (poor description of practice as relates to no. of different specimen types collected)
- **Total for outcome measures (2-pt. maximum):** 1 (recording method not described)
- **Total for results/findings (3-pt. maximum):** 2 (insufficient no. of SPA and CATH specimens included in data analysis)

#### Description
- **Design:** Cross-sectional facility/setting: teaching hospital.
- **Time period:** Not reported.
- **Population/sample:** 1,067 children, 88 younger than 1 mo, 726 between 1 and 6 mo, 318 between 7 and 24 mo, and 335 older than 24 mo of age. There were 521 (48.9%) girls. Of these 1,067 children, 951 (89.1%) were admitted to the outpatient clinic and 116 (10.9%) were admitted to the inpatient clinic.
- **Comparator:** None.
- **Study bias:** None noted.

#### Description
- **Design:** Prospective cross-sectional facility/setting: teaching hospital.
- **Time period:** Not reported.
- **Population/sample:** Children aged up to 3 yr without known UTI had urine collected by 3 different methods used consecutively, namely, clean-catch, cotton wool sanitary pad, and urine bag. 534 urine samples were obtained from 191 children. There were 124 boys (65%). The median age was 2 mo (1 day–36 mo).
- **Comparator:** Intersubject study bias: order of specimen collection not defined.

#### Description
- **Design:** 4 methods of urine collection were studied: SPA, CCU, CATH, and UB.
- **Duration:** 2 mo.
- **Training:** Nurses trained parents on UB collection. Hospital personnel were trained on proper collection of SPA and CATH specimens.
- **Staff/other resources:** Not reported.
- **Cost:** Not reported.

#### Description
- **Design:** The specimens collected by type were divided according to age group. The no. of specimens yielding significant pathogens and the no. of contaminated specimens were calculated.
- **Semiquantitative cultures were performed by routine laboratory methods. A positive urine culture was defined as the growth of a single pathogen of more than 10^5 CFU/ml in UB and CCOU specimens, >10^4 CFU/ml in urine specimens obtained by CATH, and any no. of colonies in a sample obtained by SPA. Urine cultures interpreted as "contaminated" by the laboratory were considered to be contaminated.

- **Recording method:** Not reported.

#### Description
- **Design:** The specimens collected after perineal cleaning with soap and water (all 3 collected on same day or next day if required, with the order of collection at the nurses’ discretion). The 1st was a clean-catch specimen, the 2nd was collected in a cotton pad (either sterile Newcastle or commercial sanitary pads) and aspiration with a syringe. The 3rd was collected in a Hollister urine bag taped to the infant.
- **Samples were placed in a refrigerator, transferred to sterile coded tubes, and plated within 20 min of receipt by the laboratory. Cultures were interpreted as >10^4 or <10^5 CFU/ml. Also, microscopy was performed on uncentrifuged urine.
- **Duration:** 2 mo.
- **Training:** Parents instructed by nursing on proper urine collection.
- **Staff/other resources:** Not reported.
- **Cost:** Cost of pads described.

#### Description
- **Design:** The percentage of urine samples contaminated by each collection method was based on a quantity of >10^5 or <10^5 CFU/ml, organism type, and agreement between sample types. Phase-contrast urine microscopy results were correlated with culture results.
- **Recording method:** Not reported.

#### Results/findings
- **Type of findings:** Observational findings.
- **Effect size:** 617 subjects (57.8%) had negative culture results, 145 (13.6%) had positive culture results, and 305 (28.6%) had evidence of bacterial contamination.
- **CCU and CATH specimens showed a contamination rate of 14.3%. However, urethral catheterization was performed in only a small no. of subjects (n = 7). SPA was also used in a small no. of subjects (n = 11), and the contamination rate for SPA was 9.1% (1/11). The contamination rate for sterile UB was 43.9%, significantly higher than rates for the other methods (P < 0.001).

#### Statistical significance/tests:
The data were analyzed using the Statistical Package of Social Sciences for Windows, version 10.0 (SPSS Inc., Chicago, IL, USA) program. Pearson’s r and Fisher’s exact tests were used to compare differences between groups. A P of <0.05 was considered significant.

#### Results/conclusion biases:
Parental collection of UB specimens may have contributed to a high contamination rate.

#### Type of findings:** Descriptive, comparative.
#### Effect size:** Results from 175 patients showed similar contamination rates for pads and bags but lower rates for clean-catch specimens (P < 0.01). Kappa analyses showed fair agreement between clean-catch specimens and those collected in pads/bags. The difference between sterile pads and sanitary pads was not significant. No significant differences were based on gender. Microscopy showed reasonable correlation with culture positivity.

#### Statistical significance/tests:
agreement between the tests calculated using kappa statistics. More than 40% agreement was regarded as a good level of agreement. The chi-square test was used to analyze differences in proportions.

#### Results/conclusion biases:
results limited to nonsymptomatic pediatric inpatients.

<tbody>
<tr>
<td>Authors: Macfarlane et al. (54)</td>
<td>Design: prospective cross-sectional Facility setting: teaching hospital Time period: not reported Population/sample: 2 urine samples, collected from 45 infants aged 1–23 mo, 1 with a sterile bag and 1 from a nongel diaper Comparator: bag vs diaper Study bias: only inpatients included in study, small sample size</td>
<td>Description: 2 consecutive urine samples were collected from 45 infants who were 1–23 mo old: 1 from a sterile urine bag and 1 from a nongel diaper. Diapers older than 4 h and containing feces were excluded. WBC and RBC evaluations were performed using microscopy. All specimens were processed for routine culture by the microbiology laboratory. Duration: not reported Training: not reported Staff/other resources: not reported Cost: not reported</td>
<td>Description: semiquantitative culture with standard definitions for contamination and significance (&gt;10^5 CFU/ml) Recording method: not reported</td>
<td>Type of findings: comparative Findings/effect size: UCPs resulted in an unhelpfully high rate of contamination (65%) similar to that for bag samples (68%). Only 27% of clean-catch urine samples were contaminated. Sterile urine or urine with a low (&lt;10^5 CFU/ml) mixed bacterial count is probably sufficient in most cases to rule out UTI, whereas a sample contaminated by a heavy mixed growth may hide infection. Such samples may need to be repeated. Applying this principle to our series, the authors found that 14 (27%) of 52 pad samples, 11 (32%) of 34 bag samples, but only 29 (12%) of 240 clean-catch samples would have been repeated. Statistical significance/tests: Results/conclusion biases: not reported</td>

</tbody>
</table>

| Authors: Ahmad et al. (55) | Design: observational Facility setting: teaching hospital Time period: not reported Population/sample: 88 inpatients, all below 2 yr of age, were included. 56 UCP samples were reliably obtained; the remaining 32 samples failed for a variety of reasons and were excluded. 34 children in the same age range had urine bag collection done over the preceding 9 mo. 240 clean-catch samples were analyzed (no. of children not reported); Comparator: between-patient populations Study bias: nonrandom, unequal sample sizes, no standard reference method | Description: 1. The UCP was placed inside the front of the child’s nappy; the child’s nurse checked the pad every 15–20 min, removed it when wet, and aspirated urine from it using a 20-ml syringe. Fecally soiled pads were discarded. 2. Urine from 34 children in the same age range and ward setting that had bag urine collection done over the preceding 9 mo was similarly tested. Duration: 3 mo Training: not reported Staff/other resources: not reported Cost: not reported | Description: colony counts (CFU/ml) across all sample types. Recording method: not reported | Type of findings: observational/comparative Findings/effect size: UCPs resulted in an unhelpfully high rate of contamination (65%) similar to that for bag samples (68%). Only 27% of clean-catch urine samples were contaminated. Sterile urine or urine with a low (<10^5 CFU/ml) mixed bacterial count is probably sufficient in most cases to rule out UTI, whereas a sample contaminated by a heavy mixed growth may hide infection. Such samples may need to be repeated. Applying this principle to our series, the authors found that 14 (27%) of 52 pad samples, 11 (32%) of 34 bag samples, but only 29 (12%) of 240 clean-catch samples would have been repeated. Statistical significance/tests: Results/conclusion biases: not reported |

| Authors: Macfarlane et al. Table A4 (Continued)

| Authors: Vaillancourt et al.  | Study bias: retrospective study | Comparator: clean-catch urine collection method. | Study bias: only patients with a positive urinalysis were cultured |
| Authors: Tosif et al.  | Population/sample: All toilet-trained children who were given neither a sterile urine collection container nor an instruction sheet. | Findings/effect size: A total of 350 children were enrolled. The overall prevalence of UTIs was 7%. The rate of contamination in the cleansing group was 14 (7.8%) of 179 vs 41 (23.9%) of 171 in the noncleansing group. | Type of findings: observational Findings/effect size: 1. The age range of children was less than 3 mos, with a mean age of 7 mos. Overall, most urine specimens were obtained by CATH collection (34%), followed by CATH and SPA. ED collections were by CATH (15%), SPA (14%), and unknown means of collection (9%), and unknown means of collection (9%), and unknown means of collection (9%), and unknown means of collection (9%), and unknown means of collection (9%). The chi-square test was used to test for a difference in the culture results between the cleansing and noncleansing groups among samples with a positive urinalysis result.

Type of findings: comparative Findings/effect size: A total of 350 children were enrolled. The overall prevalence of UTIs was 7%. The rate of contamination in the cleansing group was 14 (7.8%) of 179 vs 41 (23.9%) of 171 in the noncleansing group. Children who were randomly assigned to cleansing were less likely to have a positive urinalysis result (37 of 179 [20.6%]) than those in the noncleansing group (63 of 171 [36.8%]). Statistical significance/tests: RR and their 95% CI for contamination and for a positive urinalysis were calculated using SPSS 11.0 (SPSS, Chicago, IL). The chi-square test was used to test for a difference in the culture results between the cleansing and noncleansing groups among samples with a positive urinalysis result. Because the intervention was randomized by wk rather than by individual patient, a GLIMMIX was used to account for potential within-wk clustering of outcome results and to adjust for potential baseline imbalances in gender, age, and history of renal problems. The interaction terms for treatment by gender and age were also included in the GLIMMIX. Results/conclusion biases: The lack of a reference method makes assignment of true positives (infected) difficult.

Findings/effect size: 1. The age range of children was less than 3 mos, with a mean age of 7 mos. Overall, most urine specimens were obtained by CATH collection (34%), followed by CATH and SPA. ### Description:
- SPA sample collection was by using a 19-gauge needle; the skin was cleaned with iodophor, and a 2nd attempt was made if the 1st aspiration failed. MSU collection was performed under supervision after cleansing of the external genitalia. All specimens were refrigerated prior to being processed for semiquantitative culture. Samples were also processed for urine microscopy.
- Duration: not reported
- Training: SPA was performed by a trained physician; mothers were instructed on collection of MSU.
- Staff/other resources: not reported

### Recording method: not reported

### Type of findings:
- Observational/comparative

### Findings/effect size:
1. The initial attempt at SPA was successful in 260/287 patients without complication and was easy to perform.
2. MSU collection was often difficult to perform and took up to 2 h.
3. In 51 patients with paired SPA and MSU specimens, there were no false-positive or false-negative diagnoses made with sterile SPA specimens were counted.
4. A high number of contaminated specimens was found among MSU samples collected by mothers and from boys with a nonretractable prepuce.

### Statistical significance/tests: not reported

### Results/conclusion biases: none reported

### Total quality rating (10-pt. maximum): 6, fair

### Total for study (3-pt. maximum): 1 (total for study setting may not be generalizable; SPA collection by single individual)

### Total for practice (2-pt. maximum): 2

### Total for outcome measures (2-pt. maximum): 1 (recording method not reported)

### Total for results/findings (3-pt. maximum): 2 (no statistical analysis)

<td>Authors: Pylkkänen et al. (58)</td>
<td>Design: observational</td>
<td>Description: 1. Urine was collected by SPA. 2. CVU was collected from infants with urine collection bags. 3. Midstream CVU was collected from children after cleansing of genitalia with 0.05% chlorhexidine solution. All specimens were examined by microscopy. All specimens were processed on Uricult dipslides. SPA specimens were also plated on blood agar. Duration: not reported Training: not reported Staff/other resources: not reported Cost: not reported</td>
<td>Description: Cell counts were classified as ( \leq 10), 11–199, or ( \geq 200/\text{mm}^3 ). Bacterial counts were classified as nil, scanty, or numerous by microscopy and as ( &lt; 10^3 ), ( \geq 10^3 ) by quantitative culture. Urine collected by SPA was cultured on both Uricult and blood agar plates. A patient was considered infected when both cultures showed growth. Recording method: not reported</td>
<td>Type of findings: observational. Findings/effect size: CVU specimens demonstrated significant leukocyte counts, bacterial cell counts, or ( &gt; 10^5 ) CFU/ml in culture for 59%, 42%, and 81% of infected (as diagnosed by SPA) symptomatic patients. Diagnostic accuracies of these indices were 88%, 94%, and 99%, respectively. In asymptomatic patients, the accuracies were considerably lower. None of the indices gave sufficient sensitivity or accuracy when used alone. Statistical significance/tests: chi-square test. Results/conclusion biases: none reported</td>

<tr>
<td>Authors: Aronson et al. (59)</td>
<td>Design: prospective cross-sectional</td>
<td>Description: Percutaneous SPA was carried out after the suprapubic area was cleansed with alcohol and iodine. The urine was gently aspirated in a 5- or 10-ml sterile syringe and the needle withdrawn. Cleanly voided urine from infants was collected in a sterile polyethylene urine bag after previous proper cleansing of the vulva, preputial folds, and perineum. Irrigation of the vulva and prepuce was performed twice with 5 to 10 ml tepid physiologic saline. A clearly voided midstream specimen was obtained from children after a thorough cleansing as described above. Specimens were transported to the laboratory immediately for routine culture. Duration: not reported Training: not reported Staff/other resources: not reported Cost: not reported</td>
<td>Description: Urinary infection was considered to be present if the bacterial count was ( 10^5 ) CFU/ml in SPA urine (true bacteriuria). Was suspected if the bacterial count in cleanly voided urine was ( &gt; 10^3 ) CFU/ml. Shortly after collection, the uncentrifuged urine was also examined for pyuria, expressed as the leukocyte count/mm(^3). Leukocyte counts of ( &gt; 10^5 ) cells/mm(^3) in SPA urine was considered pathologica. Recording method: not reported</td>
<td>Type of findings: observational. Findings/effect size: In infants, the suspicion of infection from cleanly voided counts of ( &gt; 10^5 ) CFU/ml could be excluded by a finding of normal SPA urine for 27 babies, 4 babies had infection in their SPA urine despite having only slight or moderate bacteriuria in their cleanly voided urine. 4 patients suspected of having an infection from their cleanly voided urine proven by examination of the SPA urine, whereas 4 patients with true bacteriuria had a low bacterial count in voided urine. Misleading information about bladder urine bacteriuria was thus obtained from bacterial culture of cleanly voided specimens in 39 of 120 examined patients. Statistical significance/tests: not reported. Results/conclusion biases: Results may have been influenced by a small sample size.</td>

#### Description:
- **Authors:** Hardy et al. (56)
- **Title:** Comparison of Sterile Bag, Clean-Catch and Suprapubic Aspiration in the Diagnosis of Urinary Infection in Early Childhood
- **Affiliations:** Department of Pediatrics and Microbiology, Royal Free Hospital, London, United Kingdom
- **Funding:** not reported

**Design:** cross-sectional

**Facility/setting:** inpatient ward at a tertiary hospital

**Time period:** not reported

**Population/sample:** 30 inpatients; age range, 1 day to 3 yr. All were screened for urinary infections, with the bag technique being used for those without bladder control. If bacterial growth was obtained from the first bag specimen, the child was entered into the formal study. Also entered were patients whose condition demanded immediate antimicrobial therapy, for whom a delay caused by screening could not be justified. In the latter group, all 3 specimens were taken without screening.

**Comparator:** SPA

**Study bias:** small sample size

**Total quality rating (10-pt. maximum):** 5, fair

**Total for study (3-pt. maximum):** 2 (small sample size)

**Total for practice (2-pt. maximum):** 1 (significant bacteriuria vs contamination not defined)

**Total for outcome measures (2-pt. maximum):** 1 (recording method not reported)

**Results/findings:**
- Type of findings: observational
- Findings/effect size:
  1. In SPA specimens, there was no growth from 26 specimens and a pure growth of $10^5$ CFU/ml or more organisms from the remaining 4 specimens. It was assumed that only these 4 had significant bacteriuria.
  2. Bag and CCU specimens exhibited a high incidence (73%) of mixed growth. The mixed growth occurred from specimens that were sterile when taken by SPA.
  3. There was agreement between bag, CCU, and SPA specimens in only 3 cases of no growth, and there was 1 case with significant bacteriuria.

**Statistical significance/tests:** not reported

**Results/conclusion biases:** Results may be impacted by small sample size.

#### Description:
- **Authors:** Ramage et al. (51)
- **Title:** Accuracy of Clean-Catch Urine Collection in Infancy
- **Affiliations:** Renal Unit and Department of Diagnostic Imaging, Royal Hospital for Sick Children, and Department of Statistics, University of Glasgow, Glasgow, United Kingdom
- **Funding:** not reported

**Design:** cross-sectional

**Facility/setting:** inpatients, pediatric teaching hospital

**Time period:** not reported

**Population/sample:** 49 pediatric inpatients of $<$2 yr or $>$2 mo for whom urine culture was indicated

**Comparator:** SPA

**Study bias:** parents were involved in specimen collection process

**Total quality rating (10-pt. maximum):** 8, good

**Total for study (3-pt. maximum):** 2 (small sample size)

**Total for practice (2-pt. maximum):** 2

**Total for outcome measures (2-pt. maximum):** 1 (recording method not reported)

**Results/findings:**
- Type of findings: comparison
- Findings/effect size:
  1. Compared to SPA specimens, CCU specimens showed a false-positive rate of 5% and a false-negative rate of 12%, with a sensitivity of 94.9% (95% CI, 65.8–98.6) and a specificity of 95.0% (95% CI, 83.1–99.4).
  2. Of 16 cultures in which SPA and CCU specimens were positive, the 2 specimens that were negative by SPA but positive by CCU collection (false-positive results) demonstrated a mixed growth of $>10^5$ CFU/ml. In 2 SPA specimens demonstrating significant growth, a pure growth of $10^7$ CFU/ml was seen in one CCU culture and a mixed growth of $10^9$ CFU/ml was observed in the other (false-negative results).

**Statistical significance/tests:** chi-square test

**Results/conclusion biases:** not reported

<td>Design: prospective cross-sectional Facility/setting: outpatient clinic, pediatric teaching hospital Time period: not reported Population/sample: 38 infants aged 1 to 24 mo who presented to a pediatric ambulatory community clinic with fever Comparator: SPA or bladder CATH urine samples Study bias: potential subject selection bias; small sample size with inability to consider CATH and SPA separately (possible practice confounder) Description: all infants had urine collected either by CATH or SPA and by extraction from a disposable diaper. The urine was extracted from the diapers by removing the lining layer of the diaper under aseptic conditions using sterile tweezers, and then pushing the damp fibers into the barrel of a standard 20-ml disposable syringe from which the plunger had been removed. By replacing the plunger and compressing the fibers, urine was easily obtained from the diapers. Ultra-absorbent diapers that contain a gel-like material were excluded from the study because extracting urine from them is difficult and time-consuming. In addition, diapers contaminated with feces or those that had been on the infant for longer than 3 h were excluded. The urine samples were sent to the laboratory and were cultured using standard bacteriologic techniques Duration: not reported Training: not reported Staff/other resources: not reported Cost: not reported</td>

<td>Total for practice (2-pt. maximum): 1 (&quot;significant bacteriuria&quot; not defined vs &quot;contamination&quot;)</td>
<td>Total for outcome measures (2-pt. maximum): 1 (recording method not reported)</td>
<td>Type of findings: comparative Findings/effect size: Urinary tract infection was demonstrated by SPA or CATH specimen collection from 5 (12.5%) infants (4 female and 1 male). For all 5 children, urine cultures showed more than 10^5 CFU/ml of the same single organism from urine that had been collected from both the diapers and the SPA or CATH specimens (sensitivity of 100% [5/5]) and specificity of 94% ([31/ 33]). A statistical analysis revealed a wide CI and estimated the low end to be 55% for sensitivity and 82% for specificity. These results were derived using the binomial distribution. Statistical significance/test: A statistical analysis (method not reported) revealed a wide CI and estimated the low end to be 55% for sensitivity and 82% for specificity. These results were derived using the binomial distribution. Results/conclusion biases: The small sample size, particularly for infants with positive results, explains why the confidence limits are much lower than the estimated values.</td>

### REFERENCES

14. Schonwald B, Begovac J, Skerk V. 1994. Symptomatic urinary tract infections complicating pregnancy: a College of American Pathologists Q-Probes study of contaminated urine cultures and catheter cultures for making a clinical diagnosis of UTI. Definitions were as follows: positive urine culture for bag specimens, ≥105 CFU/ml; positive urine culture for CATH specimens, ≥105 CFU/ml (1 species only); polybacterial urine culture (considered a contaminated sample), ≥105 or ≥106 CFU/ml (depending on collection method) and >2 species present upon culture; negative urine culture, all other specimens. Recording method: not reported. Type of findings: comparison findings/efffect size: A total of 7.5% and 29% of bag-obtained specimens had positive cultures and false-negative results, respectively, compared to CATH specimens. Bag-obtained specimens led to either a misdiagnosis or an impossible diagnosis in 40% of cases vs 5.7% when urethral catheterization was used. Statistical significance/test: percentage comparisons performed using the chi-square test Result/conclusion biases: Failure to perform a successful catheterization was common. The contamination rate for CATH specimens was also higher than expected.

### ACKNOWLEDGMENTS

This work was sponsored by the American Society for Microbiology in collaboration with the Centers for Disease Control and Prevention’s Division of Laboratory Programs, Standards, and Services through a Laboratory Medicine Best Practices Program Memorandum of Understanding. The authors declare no conflicts of interest.

The findings and conclusions in this article are those of the authors and do not necessarily represent the official position of the Centers for Disease Control and Prevention or the Agency for Toxic Substances and Disease Registry (CDC/ATSDR).

### TOTAL FOR STUDY (3-PT. MAXIMUM): 2

**Total quality rating (10-pt. maximum):** 7, fair

**Total for practice (2-pt. maximum):** 2

**Total for results/findings (3-pt. maximum):** 2

* SPA, suprapubic aspiration; CCU, clean-catch urine; CVU, cleanly voided urine; CATH, straight catheterization; SUB, sterile urine bag; UCP, urine collection pad; MSU, midstream urine; ED, emergency department; HPP, high-power field; RR, relative risks; 95% CI, 95% confidence interval; GLIMMEX, generalized linear mixed model; OR, odds ratio; CLED, cystine lactose electrolyte-deficient.

Mark T. LaRocco earned his Ph.D. in microbiology from Thomas Jefferson University, Philadelphia, PA, in 1984. He completed a Committee for Postdoctoral Education Program (CPEP)-accredited postdoctoral program in medical and public health microbiology at the Baylor College of Medicine, Houston, TX, where he focused on novel methods for susceptibility testing of fungi. He held faculty positions at the University of Texas Health Sciences Center in Houston and served as director of clinical microbiology, first at Hermann Hospital and later at St. Luke’s Episcopal Hospital in Houston. He is a diplomate of the American Board of Medical Microbiology and a fellow of the American Academy of Microbiology. Dr. LaRocco later became administrative director of pathology and then vice president at St. Luke’s and is currently serving as a consultant in clinical microbiology, laboratory medicine, and hospital administration. He has over 100 publications on topics related to medical mycology, antimicrobial susceptibility testing, total quality management, and patient safety.

Jacob Franek earned his master’s degree in health sciences with a focus in community health and epidemiology from the University of Toronto in 2007. Over the last 10 years, he has held positions as senior clinical epidemiologist specializing in health technology assessment/systematic review and evidence-based methods with Cancer Care Ontario and the Medical Advisory Secretariat (now Health Quality Ontario) of the Ontario Ministry of Health and Long-Term Care and is currently serving as an internal senior consultant for Kaiser Permanente and as an external consultant in health technology assessment/systematic review, evidence grading, evidence-based decision-making, and biostatistical analysis for various organizations, including the Centers for Disease Control and Prevention and the American Society for Microbiology. Given the general lack of evidence-based guidelines across microbiology and laboratory medicine, he is interested in advancing evidence-based knowledge in these fields.

Elizabeth Kenimer Leibach has a baccalaureate degree in medical technology (M.L.S. (CM)) and a master of science degree in cell and molecular biology from Georgia Regents University, with a specialty in blood banking (S.B.B.C.M) and certification through the School of Blood Banking Technology of the University of Texas Health Sciences Center in Dallas, TX (Parkland Memorial Hospital). She also holds a doctorate of education in adult education from the University of Georgia. She is involved in clinical research in evidence-based laboratory medicine related to informatics and clinical decision support, individual- and population-level health record data analysis, and quality metrics for evaluation of medical effectiveness and cost-efficiency. She has experience in laboratory practice and administration in a variety of health care delivery settings as well as in industry and higher education, and she is currently an expert consultant for the U.S. Centers for Disease Control and Prevention. She has over 70 publications on topics related to evidence-based practice and education.

Alice Schauer Weissfeld, Ph.D., is the president, chief executive officer, and laboratory director of Microbiology Specialists Incorporated, a reference laboratory that she cofounded in 1984. She earned her doctoral degree in microbiology at Rutgers University, New Brunswick, NJ, and completed a postdoctoral fellowship in Public Health and Medical Laboratory Microbiology at Baylor College of Medicine, Houston, TX. Dr. Weissfeld is a diplomate of the American Board of Medical Microbiology of the American Academy of Microbiology and was elected to fellowship in the American Academy of Microbiology in 1986. She is currently a member of ASM’s New Professional Practice Committee and chair of its Subcommittee on Evidence-Based Medicine. The Subcommittee oversees the development of laboratory medicine best-practice guidelines using a robust, methodical, and transparent method developed by the CDC and is participating in a cooperative agreement with the CDC to evaluate metrics to encourage the dissemination of ASM’s guidelines.
Colleen S. Kraft earned her M.D. from Indiana University in 2002 and her M.Sc. from Emory University in 2013. She completed a residency in internal medicine and a fellowship in infectious diseases in the Department of Medicine, Emory University. She concluded her postgraduate clinical training in an Accreditation Council for Graduate Medical Education (ACGME) fellowship in medical microbiology in the Department of Pathology and Laboratory Medicine, Emory University. She has a joint faculty appointment at Emory University in the Department of Pathology and Laboratory Medicine and the Division of Infectious Diseases. She is the medical director of the microbiology section at Emory Healthcare and program director of the medical microbiology fellowship, and she performs rounds for the inpatient infectious diseases service. Her interests are in microbiology questions that have direct clinical implication and in the support of these practices with evidence-based methods. She has been on the faculty at Emory since 2010.

Robert L. Sautter completed his B.S. and M.S. degrees at Eastern Michigan University and received his Ph.D. in microbiology from Wayne State University in 1982. He is director of microbiology and point of care for the Carolinas Pathology Group. He has held positions that include director of the Mecklenburg County Health Laboratory and of the School of Medical Technology for Harrisburg Hospital and adjunct professor for Penn State Hershey Medical Center, as well as technologist and supervisory positions at various institutions over 43 years. Dr. Sautter serves on the North Carolina Response Advisory Group’s Hospital Acquired Infection (HAI) Advisory Committee, and he chairs the North Carolina subcommittee of the HAI committee concerning multi-drug-resistant organisms. He serves on many hospital and university committees. He has been chair of the clinical microbiology division of the American Society for Microbiology. He also served the Clinical Laboratory Improvement Advisory Committee and the Board of Scientific Counselors of the Office of Infectious Diseases at the CDC.

Vickie Baselski received her doctoral degree in microbiology from the University of Texas at Austin in 1978 and completed a postdoctoral fellowship in medical and public health laboratory microbiology at the Centers for Disease Control. She is a diplomate of the American Board of Medical Microbiology and a fellow in the American Academy of Microbiology. Her professional service activities have included technical direction of microbiology at The University of Tennessee Bowld Hospital, The Regional Medical Center at Memphis, and Memphis Pathology Laboratory/American Esoteric Laboratory. She currently provides technical direction for microbiology at the Shelby County Health Department and at Methodist University Hospital. She is a professor of pathology and laboratory medicine at the University of Tennessee Health Science Center. As chair of the Professional Affairs Committee of ASM, she has presented to federal, state, and private professional groups in areas relating to reimbursement, including issues related to emerging technologies.

Deb Rodahl is the group director for clinical support services at the HealthEast Care System in St. Paul, MN. The HealthEast Care System is a nonprofit healthcare organization which includes 4 acute-care hospitals, 15 physician clinics, and other free-standing business entities. Deb received her B.S. degree from the University of Minnesota in 1980 and her M.B.A. from Cardinal Stritch University in 2006. Deb has been with HealthEast since 1980, where she started out as a “generalist.” In 1985, she was promoted to Operations Manager for the St. John’s Laboratory. In 1992, Deb was promoted to administrative director of operations with the HealthEast Laboratories and promoted to system director of laboratory services in 1997. As a laboratory manager with responsibility for acute-care labs as well as outreach laboratory services, she has a great interest in ensuring optimal preanalytical handling of all specimens.

Edward J. Peterson, Jr., M.B.A., M.T. (American Society for Clinical Pathology), earned his bachelor’s degree in medical technology and biology from the State University of New York at Fredonia in 1983, and he completed his medical technology internship at Lenox Hill Hospital, New York, NY, in 1984 and his M.B.A. from St. Joseph’s University, Philadelphia, PA, in 1999. He is currently the director of laboratories for Barnes-Jewish Hospital in St. Louis, MO, which is affiliated with the Washington University School of Medicine. He is an assistant professor for Rutgers University and teaches a course in health care regulations and laboratory management. During his 31-year career, he has held positions as the director of regulatory affairs, facility planning, and diagnostic services (which included supervision of laboratories, radiology, and radiation oncology), as a general lab supervisor overseeing a hematology laboratory and a blood bank, and as a hematology supervisor for hospitals in New Jersey and New York. Proper collection of specimens is an area of interest to him because it will lead to improved patient outcomes.

Nancy E. Cornish received her B.A. in philosophy and M.D. from the University of Vermont, Burlington, VT; then she completed her pathology residency at the Vermont Medical Center Hospital. She completed a microbiology fellowship at the Cleveland Clinic Foundation before serving 13 years as a pathologist and the director of microbiology at the Methodist Health Care Systems & Children’s Hospital in Omaha, NE. Dr. Cornish has been active in laboratory professional organizations as a faculty member, speaker, and presenter; this includes over 20 years with the College of American Pathologists and the American Society of Clinical Pathologists and nearly 20 years with the American Society for Microbiology and the Infectious Disease Society of America. She holds certification with the American Board of Pathologists in anatomic and clinical pathology, with a special qualification in medical microbiology. Dr. Cornish is currently medical officer for the Division of Laboratory Systems at the Centers for Disease Control and Prevention.
